Abstract

I develop a heterogeneous-country model of the world economy to study the distributional impact of aggregate capital flight episodes. A global intermediary borrows from all countries and invests in their risky assets. Wealth heterogeneity between countries arises naturally due to idiosyncratic shocks. A single global factor that combines the intermediary’s wealth and risk-taking capacity determines capital inflows and risk premia in every country. A shock to the intermediary’s risk-taking capacity generates global capital flight. Investors from rich countries use their external savings to replace foreign demand for domestic assets. These countries experience a “retrenchment” event: a sizable fall in outward flows. Their risky assets appreciate on impact. In poor countries, investors cannot replace foreign demand without a sharp rise in risk premia. Their asset markets adjust through prices rather than quantities, and prices fall. Estimating the model, I find that global financial shocks explain a quarter of the time-series variation in aggregate capital flows and a third of the variation in the relative performance of assets in advanced economies compared to emerging markets.

Key Words: capital flows, risk premium, global financial cycle, heterogeneity, retrenchment

JEL Classification Numbers: F32, F44, G12, G15

*I thank my advisors Fernando Álvarez, Mikhail Golosov, Lars Peter Hansen, and Guido Lorenzoni. I also thank Francesca Bastianello, Jaroslav Borovička, Maryam Farhoodi, Zhiyu Fu, John Heaton, Elena Istomina, Greg Kaplan, Rohan Kekre, Paymon Khorrami, Yueran Ma, Esteban Rossi-Hansberg, Robert Shimer, Marcos Sora, and all seminar participants.
1 Introduction

There is an aggregate cycle in international capital flows and asset prices. One factor explains 20% of the variation in gross capital flows across the world. This factor is strongly correlated with an equally powerful dominant factor in asset prices and various measures of global risk-taking capacity. In booms, when asset prices are high, investors tend to accumulate foreign assets. In global downturns, they sell foreign assets and shift their portfolios toward domestic markets, which is what the literature calls “retrenchment”.

Countries are not equally exposed to the global cycle. Emerging markets and developing economies are especially strongly affected by changes in the risk appetite of foreign investors. Asset prices are generally more volatile in these countries. At the same time, gross capital flows tend to be more strongly correlated with global aggregates in advanced economies. In downturns, investors from advanced economies sell more of their foreign assets than those from emerging markets, responding to negative shocks with more active retrenchment.

I construct a dynamic multiple-country model with a global financial cycle to interpret these patterns. I then use the model to quantify the differential impact of global shocks on advanced economies and emerging markets, jointly explaining the data on capital flows and asset prices.

Motivated by the strong correlation between aggregate capital flows and measures of global risk appetite, I center the model around global intermediaries that trade risky assets in all countries. I then focus on capital flight episodes triggered by shocks to their risk-taking capacity. These episodes generate an aggregate fall in demand for risky assets. Following the literature, I call them “risk-off” events. My first objective is to explain cross-country heterogeneity in their impact.

I propose retrenchment as a mechanism that generates this heterogeneity. In the model, the response of domestic investors determines the dynamics of asset prices in capital flight events. When the global intermediary has low risk-taking capacity, it sells risky assets in all countries. In rich countries, domestic investors readily buy local assets using their large external savings. This supports domestic asset prices, while the country’s external assets and liabilities fall at the same time. In poor countries, domestic investors are too poor to absorb the shortfall in foreign demand. Their asset markets mainly adjust through prices rather than quantities. This concentrates the rise in risk premia in poor countries, while retrenchment happens in rich ones.

The model uses the following ingredients to generate this pattern. There is a continuum of countries. In each one, there is an asset with idiosyncratic shocks to payoffs and a local agent who trades this asset with the global intermediary. The intermediary issues bonds to the local agents. Markets for risky assets are segmented: local agents cannot directly access other countries. The two other markets, for intermediary’s bonds and for the single consumption good, clear globally.

The intermediary’s risk-taking capacity is limited. Even though it has access to a continuum of uncorrelated risky assets, it cannot take advantage of full diversification. The reason is that it is
unsure about the right model for country-specific shocks and takes a cautious approach to investing, considering worst-case scenarios. This behavior reduces to a simple value-at-risk constraint that makes the intermediary treat idiosyncratic risk as a real concern and gives it a risk-return trade-off for every country in its portfolio. The intermediary’s risk-taking capacity can be summarized by one preference parameter that varies over time, driving global dynamics.

Since the intermediary cannot fully absorb country-specific shocks, risk-sharing between countries is incomplete. In equilibrium, exposure to domestic idiosyncratic shocks creates a wealth distribution between countries, and asset prices depend on wealth accumulated by local agents.

There is a simple formula for the equilibrium risk premium on each country’s asset. Risk premia depend on local wealth and on one global factor that is common to all countries. This global factor combines the intermediary’s fundamental risk-taking capacity and its net worth. Demand for risky assets depends both on fundamental preferences for risk and available investment capital.

The sensitivity of a country’s risk premium to the global factor is low when the country is rich. Local investors only need a small rise in risk premium to absorb large quantities of domestic assets should the intermediary want to sell them. In poor countries, domestic investors are small, so they need a large increase in leverage to replace foreign demand. This leads to a sharp rise in risk premium every time the intermediary seeks to unload local risk.

When a negative shock hits the intermediary’s risk-taking capacity, it seeks to sell risky assets in all countries simultaneously. In rich countries, local investors buy sizeable quantities, keeping risk premia low. In poor countries, local buying power is limited, and risk premia rise to convince the intermediary to sell less. This leads to starkly different responses of asset prices in equilibrium.

Assets in rich countries appreciate on impact. The reason is that the global interest rate falls after the shock, and it falls by more than risk premia in rich countries rise. This fall in the interest rate is needed to clear the market for consumption goods since aggregate output is fixed but agents feel poorer due to falling asset prices and want to consume less. In poor countries, the rise in risk premia is too high, and it dominates the effect of the interest rate. Asset prices go down on impact.

The fact that assets in rich countries appreciate after a negative risk-taking capacity shock makes them observationally similar to a “safe asset”. They provide their owners with insurance against global risk-off events. This happens despite the fact that fundamental dividend risk is the same in all countries. Retrenchment flows alone can make assets perform like “safe” ones.

Indirectly, rich countries insure poor countries as well. The intermediary makes capital gains on assets in rich countries, which limits the fall in its net worth. This, in turn, limits the contraction in foreign demand faced by poor countries. This echoes the pattern documented by Gourinchas and Rey (2022) for the US and the rest of the world: the US provides insurance to other countries but still increases its wealth share in downturns. My model offers a way to expand this discussion and include rich countries providing insurance to poor ones.

After showing the key mechanism, I take the model to data. The quantitative version has
three additional features. First, local agents face a portfolio constraint. The risky share of their portfolios is bounded from above, which, in particular, prevents them from borrowing large amounts to increase leverage in downturns. Agents in poor countries now have even less capacity to buy assets from the intermediary in a capital flight episode, and their exposure to risk-off shocks rises.

Second, I introduce the US as a special country endowed with its own asset. Its price rises in risk-off events due to the fall in the interest rate, providing the intermediary with capital gains and increasing its wealth share. The dynamics of the intermediary’s wealth share in downturns are qualitatively important since it is a large investor in all markets, so it is essential for the model to agree with the data in this regard. I interpret the intermediary as the US financial sector, and in the data, the US takes losses on its external position but becomes relatively richer in downturns. Giving the intermediary access to domestic US assets helps the model reproduce this.

Finally, I introduce dividend shocks to the model. These shocks change aggregate output and can be called “real” as opposed to “financial” shocks to the intermediary’s risk-taking capacity. In this more complete environment, I quantify the importance of these two types of shocks for the dynamics of financial flows, asset prices, and their heterogeneity across countries.

I estimate the model on aggregate capital flow and asset returns data. Estimation uses global averages of flows and prices, but the model successfully reproduces the differences between advanced economies and emerging markets, which correspond to rich and poor countries. It generates a larger volatility of outward flows from advanced economies, where outward flows are measured as a share of external assets, and a larger volatility of asset returns in emerging markets.

Another set of important patterns are correlations of outward flows and asset returns with global aggregates. Both in the model and in the data, outward flows in advanced economies fall by more when aggregate capital flows recede, indicating more active retrenchment. In accordance with the key mechanism, assets in advanced economies outperform those in emerging markets exactly in these times. Retrenchment insulates domestic asset prices from global shocks.

The model ascribes more than half of the variation in aggregate capital flows to real shocks. Financial shocks explain only about a quarter of it. Almost all variation in aggregate returns on risky assets is due to real shocks as well.

At the same time, financial shocks are more important for the relative performance of assets in rich compared to poor countries. Real shocks move all asset prices in the same direction, while the loadings on financial shocks in rich and poor countries have opposite signs. Rich countries outperform poor ones in times of low risk-taking capacity. Quantitatively, the model can explain half of the time-series variation in the relative performance of risky assets in advanced economies compared to emerging markets. Financial shocks alone can explain a third.

Finally, the fact that prices of risky assets in advanced economies rise in response to negative financial shocks decreases their cyclicality compared to emerging markets. Overall, asset prices are positively correlated with capital flows. In poor countries, the model delivers a correlation close to
one: both real and financial shocks raise prices in times of high outward flows. In rich countries, the model-implied correlation is three times lower, since prices respond positively to output booms and negatively to booms in the intermediary’s risk-taking capacity.

**Related literature.** A large literature explores global drivers of international capital flows and asset prices. Miranda-Agrippino and Rey (2022) provide a comprehensive review. The dominant global factor in a large panel of risky asset prices has been extracted by Miranda-Agrippino et al. (2020) and more recently updated by Miranda-Agrippino and Rey (2020). Habib and Venditti (2019) find a similar global component driving stock prices around the world. Jordà et al. (2017) document co-movement between risk-premia across the world.

Similarly strong co-movement has been documented for capital flows. Forbes and Warnock (2012) and Forbes and Warnock (2021) show co-movement between gross flows. Barrot and Serven (2018) identify common components in gross flows and show that these common components are strongly related to aggregate variables such as VIX, US dollar exchange rate, and interest rates. The main one is strongly correlated with the dominant factor in risky asset prices. Davis et al. (2021) show that these factors also explain a large share of variation in net flows.

Part of this literature deals with heterogeneity between advanced economies and emerging markets. Avdjiev et al. (2022) show that synchronization between inflows and outflows is driven by banks, who are responsible for a larger share of flows in advanced economies as opposed to emerging markets. Barrot and Serven (2018) and Cerutti et al. (2019) show that flows in advanced economies are more responsive to common factors. I perform a simplified version of their factor extraction exercise to illustrate the differences in synchronization. I show that the dominant factor explains a larger share of variation in advanced economies and find that the cyclical component of flows, properly adjusted for size, in this group has a larger magnitude. This fact is at the heart of the model, which is built to generate more elastic asset markets in rich countries.

The literature studying distributions of returns and flows includes Chari et al. (2020), Gelos et al. (2022), and Eguren Martin et al. (2021). Kalemli-Özcan (2019) and Bräuning and Ivashina (2020) show that US monetary policy spillovers have a more pronounced effect on emerging markets. Chari et al. (2020) show the outsized effect of risk-off episodes on the worst realizations, the left tail. This is the response to a shock to risk-taking capacity in my model: the left tail of returns shifts significantly further, while the average stays very close to normal times.

Another strand of literature documents the special position of the US in the global financial system. Gourinchas et al. (2019) review evidence on various dimensions of its dominance. Gourinchas and Rey (2022) find that the US earns significant net returns on its net foreign asset position. Similarly to this gap between the US and the rest of the world, there is heterogeneity within the latter. Adler and Garcia-Macia (2018) show substantial differentials in returns on net foreign asset positions between advanced economies and emerging markets. My model assumes a special position of the US but generates the differences between other economies endogenously.
I contribute to the theoretical literature on the global financial cycle. The most closely related papers are Caballero and Simsek (2020a), Morelli et al. (2022), Bai et al. (2019), Davis and Van Wincoop (2022), Davis and Van Wincoop (2023), and Dahlquist et al. (2022).

Caballero and Simsek (2020a) show how retrenchment stabilizes domestic asset markets in a model where countries invest in each other’s risky assets. Liquidity shocks trigger fire sales by foreign investors. Local investors then use their foreign holdings to pick up the unwanted asset and support its price. This mechanism is also present in Jeanne and Sandri (2023). I build a dynamic version of this model in the style of Brunnermeier and Sannikov (2014) with global intermediaries and endogenously arising differences in wealth, with the main focus on the distributional consequences of aggregate capital flight.

Morelli et al. (2022) model an economy built around a global intermediary that invests in many emerging markets. They find that shocks to the intermediary’s net worth are an important determinant of borrowing costs around the world. Bai et al. (2019) use a similar model to measure the relative importance of global and local shocks in explaining the cross-section of sovereign spreads. I also study risk-off episodes driven by global intermediaries but focus on capital flows by local investors and their equilibrium implications.

Davis and Van Wincoop (2022) construct a multicountry model to generate gross flows after a shock to global risk aversion and show the importance of within-country heterogeneity. Davis and Van Wincoop (2023) additionally show that symmetric shocks to identical countries can generate positive co-movement between gross flows in and out as long as more risk-tolerant investors invest more abroad. I focus instead on the distributional consequences of global shocks in intermediated markets with endogenous heterogeneity between ex-ante identical countries.

Dahlquist et al. (2022) build a multicountry model with home-biased consumption and time-varying appetites for risk coming from deep habits. They show how an adverse output shock in a large country leads to an appreciation of its currency and, consequently, an increase in its wealth share, as its stock prices fall by less than foreign ones when adjusted for the exchange rate. I arrive at regressive redistribution in downturns through capital flows and without exchange rate fluctuations. In relative terms, rich countries become richer because they are able to compensate for the falling demand from abroad. In absolute terms, they become richer because the shock to risk-taking capacity decreases the interest rate, while risk premia are held down by retrenchment, and asset prices rise. This happens in rich regular countries as much as in the special one.

Farboodi and Kondor (2022) study heterogeneous boom-buts dynamics with imperfect information about asset quality. In their model, shocks determine what investors learn about firms. In bad times, they flee from emerging markets to advanced economies, inducing a recession in the former and stabilizing output in the latter the latter. Fu (2023) models joint determination of capital flows and exchange rates. He shows that currency betas are lower in countries where domestic investors have a higher propensity to retrench than foreign ones. The resulting link between
retrenchment and cyclicity of returns is similar to that in my model.

Market structure in my model is what Chernov et al. (2023) refer to as intermediated markets dominated by local shocks. Intermediaries operate under a single balance sheet constraint in the terminology of Siriwardane et al. (2022). The fact that country-specific returns in my model load on one global and one local factor is consistent with findings of Lustig et al. (2011) for the foreign exchange setting. Aguiar and Gopinath (2007) argue that emerging markets exhibit frequent shocks to trend growth. Hassan et al. (2021) identify spikes in perceived country-specific riskiness and show that they are associated with falling asset prices and capital flight. Amiti et al. (2019) find that local shocks are especially important for bank flows in crises.

A related strand of literature studies financial globalization in a world with country-specific shocks and imperfect financial development. Mendoza et al. (2007) find adverse welfare effects of globalization for poorer countries that lag in the development of financial markets. Bengui et al. (2013) study cross-country risk sharing, and Mendoza and Quadrini (2023) study the implication of changes in external flows between advanced economies and emerging markets.

The role of intermediaries in the model is similar to that in Gourinchas et al. (2022), where they perform international arbitrage across otherwise disjoint markets. Other models with traders intermediating international asset markets include Jeanne and Rose (2002), Gabaix and Maggiori (2015), Greenwood et al. (2020), Fanelli and Straub (2021), and Itskhoki and Mukhin (2021).

Models with the US as a special country include, among others, Bruno and Shin (2015), Maggiori (2017), Farhi and Maggiori (2018), Jiang et al. (2020), Kekre and Lenel (2021), and Sauzet (2023). In Maggiori (2017), the US faces laxer financial constraints. In Jiang et al. (2020) and Kekre and Lenel (2021), the dollar carries a convenience yield. Kekre and Lenel (2021) study flight to safety caused by a shock to this convenience yield in a model with nominal frictions and investment. Sauzet (2023) generates a rise in global risk premia and an appreciation of the dollar in times of stress with general recursive preferences and a less risk-averse US.

Aversion to ambiguity in my model is built on the large theoretical literature dating back to Anderson et al. (2000), Hansen and Sargent (2001), and Chen and Epstein (2002). More recently, Ilut and Saijo (2021) use a similar specification in a model with a continuum of firms to generate empirically relevant co-movements and cyclical patterns in a business cycle model.

On the technical side, I use heterogeneous-agent tools that have mostly been used to model separate countries. I employ methods from Kaplan et al. (2018) to analyze non-linear solutions for aggregate one-time unanticipated shocks. Sequence-space methods of Auclert et al. (2021) and Auclert et al. (2020) and insights from Bhandari et al. (2023) adapted to continuous time allow me to speed up computations and linearize the model for estimation.

**Layout.** Section 2 shows a version of the model with the main mechanism. Section 3 presents the full model, Section 4 describes equilibrium, and Section 5 treats the shocks in detail. Section 6 explains estimation and results. Section 7 performs quantitative analysis with counterfactuals.
2 Simple Model

This section presents a simple model that delivers key insights with the necessary ingredients only. I set up an economy with heterogeneous countries and study an aggregate capital flight episode. Section 3 then adds other elements of the full model.

Time is continuous and runs forever. There is no aggregate uncertainty. The world is a unit measure of countries indexed by $i \in [0, 1]$ and a large special country populated by intermediaries. Each country has a Lucas tree. Output is homogeneous across countries and stochastic. Cumulative output of $i$’s tree up to time $t$ is denoted by $y_{it}$, and flow output is $dy_{it} = \nu dt + \sigma dZ_{it}$. Expected output $\nu$ and volatility $\sigma$ are constant. The random increments $dZ_{it}$ are standard Brownian. They are independent across countries.

Agents from these countries only invest in their domestic trees and bonds issued by global intermediaries. Bonds are riskless and short-term, paying interest $r_{it} dt$. The share price of $i$’s tree is an endogenous stochastic process $p_{it}$. The instantaneous excess return on trees is

$$dR_{it} = (dy_{it} + dp_{it})/p_{it} - r_{it} dt$$

It includes dividends and capital gains. The wealth $w_{it}$ of an individual saver from country $i$ is her holdings of the tree and intermediary’s bonds. The aggregate wealth of country $i$ is $w_{it}$. In equilibrium, it equals $w_{it}$. The evolution of $w_{it}$ is

$$dw_{it} = (r_{it}w_{it} - c_{it})dt + \theta_{it}w_{it}dR_{it} + \frac{w_{it}}{w_{it}} \cdot \hat{\lambda} \hat{w}_t dt - \frac{w_{it}}{w_{it}} \cdot \lambda w_{it} dt \tag{1}$$

Here $c_{it}$ is consumption. The second term represents returns on the tree, where $\theta_{it}$ is its portfolio share. The third and fourth terms reflect exogenous migration in and out of the country. They do not affect consumption and portfolio choice. I only need them to induce stationarity. Appendix D shows another way to achieve that, using discount rates that depend on wealth.

The third term represents immigration. Intermediaries die with intensity $\lambda$, and their money is sent to one of the countries, where it is shared between local agents. The destination country is chosen uniformly, so each country $i$ has an influx of wealth $\hat{\lambda} \hat{w}_t dt$, where $\hat{w}_t$ is the total wealth of intermediaries. Within $i$, each saver gets a share $w_{it}/\hat{w}_t$ of this transfer.

The last term represents the opposite process, emigration. Agents in all countries die with intensity $\lambda$, and their wealth moves to intermediaries. The total outflow of money from $i$ is $\lambda w_{it} dt$. New agents are born instead. They start with zero wealth and instantly get transferred a portion of everyone’s savings so that everyone in the country has the same net worth. This redistribution from continuing agents is in proportion to their $w_{it}$. Hence, survivors always make flow payments $w_{it}/w_{it} \cdot \lambda w_{it} dt = \lambda w_{it} dt$ to the newborns.
The sequence problem of the saver in the country $i$ is
\[
\max_{\{c_{is}, \theta_{is}\}_{s \geq t}} \mathbb{E}_t \left[ \rho \int_t^\infty e^{\rho(s-t)} \log(c_{is}) ds \right]
\]
subject to equation (1). Since everyone has the same $w_{it}$, in equilibrium $w_{it} = \bar{w}_{it}$, and
\[
dw_{it} = (r_tw_{it} - c_{it}) dt + \theta_{it} \bar{w}_{it} dR_{it} + (\hat{\lambda} \hat{w}_t - \lambda w_{it}) dt
\]

**Intermediaries.** I use hats for intermediaries throughout. The wealth of the representative intermediary is its holdings of trees less bonds outstanding. Individual wealth $\hat{w}_t$ evolves as
\[
d\hat{w}_t = (r_t \hat{w}_t - \hat{c}_t) dt + \int \hat{\theta}_{it} \hat{w}_t dR_{it} + \frac{\hat{w}_t}{\bar{w}_t} \cdot \lambda w_t dt - \frac{\hat{w}_t}{\bar{w}_t} \cdot \hat{\lambda} w_t dt
\]
(2)

Here $\hat{c}_t$ is consumption and $\hat{w}_t$ is the aggregate wealth of intermediaries. The second term is excess returns on trees in all countries with portfolio weights $\{\hat{\theta}_{it}\}$.

The last two terms mirror migration terms in equation (1): there is an inflow $\lambda \bar{w}_t dt$, where $w_t = \int w_{it} di$ is the aggregate wealth of all countries, and an outflow $\hat{\lambda} \hat{w}_t dt$. Again, as in all countries, newborn intermediaries immediately receive transfers from survivors so that everyone’s wealth is the same.

The intermediary’s risk-taking capacity is limited. It faces a value-at-risk constraint:
\[
\int \nabla [\hat{\theta}_{it} \hat{w}_t dR_{it}] di \leq \gamma_t \int \mathbb{E} [\hat{\theta}_{it} \hat{w}_t dR_{it}] di
\]
(3)

This constraint aggregates idiosyncratic uncertainty over the intermediary’s returns in all countries and bounds it by a multiple of expected profits on these assets. In Section 3, I derive it from ambiguity aversion and explain why it is reasonable to associate it with value at risk.

The parameter $\gamma_t$ is key. It determines the intermediary’s ability to hold country-specific risk. I call it risk-taking capacity. The intermediary could in principle take advantage of access to a continuum of uncorrelated assets and fully insure other agents, absorbing all idiosyncratic risk. This case is nested as $\gamma_t = \infty$. With a finite $\gamma_t$, I can study non-trivial portfolios and trigger capital flight episodes by temporarily lowering it. The problem of the intermediary is
\[
\max_{\{\hat{c}_s, \hat{\theta}_s\}_{s \geq t}} \mathbb{E}_t \left[ \hat{\rho} \int_t^\infty e^{\hat{\rho}(s-t)} \log(\hat{c}_s) ds \right]
\]
subject to equation (2) and equation (3). Since $\hat{w}_t = \hat{\bar{w}}_t$ in equilibrium, wealth evolves as
\[
d\hat{w}_t = (r_t \hat{w}_t - \hat{c}_t) dt + \int [\hat{\theta}_{it} \hat{w}_t dR_{it}] di + (\lambda w_t - \hat{\lambda} \hat{w}_t) dt
\]
Market clearing and equilibrium. Denote bond holdings of country $i$ by $b_{it}$ and their holdings of domestic trees by $h_{it}$. By construction, $i$’s wealth is $w_{it} = b_{it} + p_{it}h_{it}$, and the risky share $\theta_{it}$ determines the split: $\theta_{it}w_{it} = p_{it}h_{it}$ and $(1 - \theta_{it})w_{it} = b_{it}$. To track the intermediary’s holdings of trees and bond issuance, let $\hat{b}_t$ be the total bonds issued and $\{\hat{h}_i\}$ be its holdings of trees. By construction, $\hat{w}_t = \int p_{it}\hat{h}_idt - \hat{b}_t$. Portfolio weights $\{\hat{\theta}_i\}$ satisfy $\hat{\theta}_i\hat{w}_t = p_{it}\hat{h}_it$ for all $i$.

Figure 1: Schematic balance sheets of agents from a country $i$ and the global intermediary.

Now market clearing conditions can be stated. Markets for trees clear locally for all $i \in [0, 1]$: 

$$h_{it} + \hat{h}_it = 1$$

Markets for intermediary’s bonds and consumption goods clear globally:

$$\int b_{it}di = \hat{b}_t$$

$$\int c_{it}di + \hat{c}_t = \nu$$

Equilibrium is a set of processes of prices $\{p_{it}, r_t\}$ and quantities $\{h_{it}, \{\hat{h}_i\}, \{b_{it}\}, \hat{b}_t, \{c_{it}\}, \hat{c}_t\}$ such that all agents make optimal choices and these markets clear.

There is only idiosyncratic uncertainty in this economy. Only agents from country $i$ and the intermediary have access to country $i$’s tree, so excess returns $dR_{it}$ only load on $dZ_{it}$:

$$dR_{it} = \mu_{it}^R dt + \sigma_{it}^R dZ_{it}$$

Drift and volatility $(\mu_{it}^R, \sigma_{it}^R)$ are equilibrium objects. Expected excess return is $\mu_{it}^R = (\nu + \mu_{it}^p)/p_{it}$, and the volatility is $\sigma_{it}^R = (\sigma + \sigma_{it}^p)/p_{it}$. Here $(\mu_{it}^p, \sigma_{it}^p)$ are drift and volatility of asset prices: $dp_{it} = \mu_{it}^p dt + \sigma_{it}^p dZ_{it}$. As usual, volatility has an exogenous and an endogenous component.

The saver’s problem has a particularly simple solution because of log utility. Agents always consume a constant fraction of their wealth and choose a mean-variance portfolio:

$$\theta_{it} = \frac{\mu_{it}^R}{(\sigma_{it}^R)^2}$$
Unit elasticity of intertemporal substitution leads to a constant consumption-wealth ratio. Unit relative risk aversion in addition leads to portfolio choice with no hedging motive.

The intermediary’s portfolio choice is similar:

\[ \hat{\theta}_{it} = \gamma_t \frac{\mu_{it}^R}{(\sigma_{it}^R)^2} \]

There is no real aggregate risk to its payoffs. Aversion to idiosyncratic uncertainty is due to the value-at-risk constraint. Its particular form obviates hedging motives, leading to a mean-variance portfolio with \( \gamma_t \) acting as time-varying risk tolerance.

Market clearing for each country’s tree leads to the following expression for risk premium:

\[ \mu_{it}^R = (\sigma_{it}^R)^2 \cdot \frac{p_{it}}{\gamma_t \hat{w}_t + w_{it}} \]  \hspace{1cm} (4)

The price of risk equals the total market cap \( p_{it} \cdot 1 \) divided by the total demand \( \gamma_t \hat{w}_t + w_{it} \), which is the sum of wealth weighted with effective risk tolerance coefficients. This risk price thus has a local component and a global component \( \gamma_t \hat{w}_t \). I denote this product by \( \varphi_t = \gamma_t \hat{w}_t \) and call it the global factor. A change in this global factor moves all risk premia simultaneously, although to a different extent that depends on local wealth.

A useful benchmark is the case with \( \gamma_t = \infty \). I describe it in Appendix F. In this case, nothing prevents the intermediary from taking advantage of a fully diversified portfolio in which country-specific risk washes out. Equation (4) shows that expected excess returns \( \mu_{it}^R \) have to be zero in equilibrium. Otherwise, the intermediary would demand assets in unbounded quantities. Since \( \mu_{it}^R = 0 \), local agents are unwilling to hold any domestic assets because for them country-specific risks are a real concern. As a result, the intermediary holds the entire global supply of risky assets. Local agents are not exposed to risk and all have the same wealth in the long run.

When \( \gamma_t \) is finite, the intermediary is only willing to take idiosyncratic risk for a positive compensation. Local agents have to absorb the rest. Exposure to country-specific shocks makes history matter for their wealth, and there is a non-degenerate wealth distribution in equilibrium.

Poorer countries have less wealth in the market for their trees, which depresses prices. Excess returns are high. Trees take a larger share of the saver’s portfolio, but the saver herself is small, and the intermediary dominates the market. The risk premium in equation (4) is more sensitive to \( \varphi_t \) since there is less wealth available to absorb fluctuations in the intermediary’s demand.

As a country grows richer after a sequence of good shocks, the price of its tree rises, and excess returns fall. The tree takes up less of the local saver’s portfolio, but the saver herself becomes so large that she takes over the market. The risk premium compresses, since the total amount of risk is negligible for very large agents. It is also less sensitive to \( \varphi_t \) since large domestic wealth can compensate for shifts in the intermediary’s demand.
**Steady state.** It is convenient to illustrate heterogeneity in a steady state with a constant $\gamma_t = \gamma$ and all other aggregates. Idiosyncratic shocks continually move countries across the steady-state wealth distribution. All country-specific variables are functions of their current wealth $w_{it}$ only.

Figure 2: Panel (a): dividend-price ratio (solid), and the interest rate (dashed). Panel (b): elasticity of the risk price in equation (4) to $\varphi = \gamma \hat{w}$. Steady-state distribution in the background.

Appendix G.1 provides details of the calibration for this numerical example. Figure 2 shows the dividend-price ratio and the elasticity of the risk price to $\varphi$ as functions of the country’s wealth. The dividend-price ratio decreases in wealth, reflecting a larger capacity of rich agents to absorb risk overall. The elasticity of risk premium to $\varphi$ is negative and increases in wealth, reflecting a larger capacity of rich agents to absorb additional supply should the intermediaries leave.

In the limit of zero wealth, the intermediary is the only investor, and the elasticity of the risk price in equation (4) to $\varphi$ is $-1$. In the limit of infinite wealth, local agents fully absorb domestic risk, and the risk premium is not sensitive to $\varphi$ at all. This difference between rich and poor countries is the key driver of heterogeneous responses to capital flight.

Importantly, non-trivial capital flows happen even in the steady state, not only in times of aggregate capital flight. Consider the steady-state consumption of the intermediary:

$$\hat{c} = \nu \cdot \int \hat{h}_{it} di - r \cdot \int b_{it} di + \int \mu^p_{it} \hat{h}_{it} di$$

The intermediary consumes the dividends, pays out interest on bonds, and realizes profits from trading. These profits come from the drift in prices $\mu^p_{it}$. Average drift is zero in the steady state, $\int \mu^p_{it} di = 0$, but the intermediary takes positions $\hat{h}_{it}$ that skew towards growing, high-yielding countries: $\int \mu^p_{it} \hat{h}_{it} di > 0$. As idiosyncratic shocks reschedule the wealth distribution, these countries become richer, their assets appreciate, and the intermediary sells them to buy cheaper assets from countries that arrive to the left tail.

An aggregate capital flight is different in that the intermediary leaves all countries simultaneously. I trigger this episode by shocking its risk-taking capacity.
**Shock to risk-taking capacity.** For illustration, suppose the economy is at the steady state at $t < 0$ and consider an unanticipated transitory shock to $\gamma$. For $t \geq 0$,

$$\gamma_t = \gamma - \Delta \gamma e^{-\mu_t}$$

I choose $\Delta \gamma > 0$ so that the shock to risk-taking capacity is negative, and demand falls.

The intermediary seeks to sell trees in all countries. Given returns, its desired portfolio share falls in the same proportion for every $i$. Local agents react, trying to absorb the unwanted assets. Their ability to do it depends on wealth. In rich countries, there is enough wealth to replace foreign demand without a dramatic rise in returns. Local agents buy trees from the intermediary, and the risk premium responds to $\gamma_t$ less than in poor countries, as equation (4) shows.

These “first round” effects capture most of the difference in responses of risk premia across the distribution, although they do not account for other moving parts in equation (4). To get the full picture, one needs to incorporate the changes in prices $p_{it}$, the intermediary’s net worth $\hat{w}_t$, and volatility $\sigma_{it}^R$. Quantitatively, these effects are less important than the direct effect of $\gamma_t$.

The ultimate object of interest is asset prices. Their response depends on what happens to the interest rate as well as risk premia. The interest rate falls on impact. This is because a fall in asset prices makes agents feel poorer, and they want to consume less. Output is fixed, however, so the interest rate falls to induce consumption.

![Figure 3: Panel (a): price change on impact (in percent of the steady-state value) with contributions of foreign demand $\varphi_t = \gamma_t \hat{w}_t$ and the interest rate $r_t$. Panel (b): change in tree holdings by domestic agents $\theta_{it} w_{it}$ on impact. Both responses as functions of $w_{it}$ right before the shock.](image)

This fall in the interest rate revalues assets. How important is this for asset prices relative to the shifts in risk premia? Panel (a) in Figure 3 shows contributions of foreign demand $\varphi_t$ and the interest rate $r_t$ to the initial response of prices. In rich countries, the impact of the interest rate dominates, and prices go up. Their assets are risky but act like colloquial safe assets since they load negatively on the intermediary’s risk-taking capacity. In poor countries, the contribution of foreign demand $\varphi_t$ dominates, and prices fall.
Panel (b) on Figure 3 shows the role of retrenchment by local agents. They increase their holdings $\theta_{it} w_{it}$, replacing foreign demand. Around zero wealth, the increase in holdings is close to zero. Even a large increase in leverage $\theta_{it}$ is ineffective if wealth $w_{it}$ itself is small. Adjustment to the shock happens through prices rather than quantities, which is reflected in the large effect of $\varphi_t$ on panel (a). In rich countries, the impact of foreign demand on prices vanishes because quantities adjust. Retrenchment of local agents insulates asset prices from the shock.

This key insight survives in the full model that is more suitable for quantitative analysis. Local wealth determines the exposure of asset prices to global financial shocks. Retrenchment compresses local risk premia, and risky assets in rich countries behave like safe assets in general equilibrium. Appendix A shows empirical support for this mechanism, documenting that outward flows in advanced economies are more strongly correlated with global aggregates in the data.

3 Full Model

I add three ingredients to the model to improve its quantitative performance. First, I introduce a portfolio constraint on local savers. In Section 2, savers from poor countries borrow from global intermediaries, and this borrowing intensifies when $\gamma_t$ falls. Intermediaries lend to poor countries to enable them to buy back their trees. Qualitatively, it does not change the fact that they are too small to insulate domestic risk premia from the shock. Quantitatively, the ability to borrow in downturns does make a difference for prices and other aggregates in general equilibrium.

Second, I add assets to the large special country where the intermediaries are domiciled. This country represents the US. In Section 2, intermediaries only hold foreign assets, but US assets are important for wealth dynamics in the data. Dahlquist et al. (2022) find that the US wealth share increases in downturns, even though it takes losses on its net foreign asset position. The reason is that its domestic market outperforms foreign markets more than enough to cover this international wealth transfer. What happens to the intermediary’s net worth after shocks bears qualitative and quantitative significance, so I add US assets to the model to be able to reproduce this fact.

Finally, I work out the problem of the intermediary to incorporate ambiguity aversion. The intermediary is unsure about the right model for country-specific risk and takes a cautious approach to investing in risky assets. This feature prevents it from taking advantage of a continuum of uncorrelated assets and does it in exactly the same way as the value-at-risk constraint from Section 2. I elaborate on the tight link between the two approaches.

Portfolio constraint. Local savers solve the same problem as before with one more restriction:

$$\theta_{it} \leq \bar{\theta}$$

It caps the share of risky assets in their portfolio. The interpretation depends on the value of $\bar{\theta}$. 
If $\vartheta = 1$, the saver simply cannot borrow from the intermediary. If $\vartheta > 1$, she can borrow from the intermediary up to a limit of $(\vartheta - 1)w_{it}$. Since the multiple $\vartheta$ of her wealth is the tree holdings, this means that borrowing is limited by $(\vartheta - 1)/\vartheta < 1$ of their market value. Finally, if $\vartheta < 1$, the saver must keep at least $1 - \vartheta$ of her wealth in riskless bonds. In this case, savers can be interpreted as including insurers and pension funds, who are mandated to hold some safe assets.

The reaction of constrained savers to foreign demand flight is the same in all three cases: they cannot buy what foreign investors wish to sell. Adjustment through prices rather than quantities takes an extreme form. However, the value of $\vartheta$ matters for the level, as opposed to dynamics, of a constrained country’s leverage. In my calibration, the relevant case is $\vartheta < 1$, when all countries, including constrained ones, have at least some foreign savings.

The saver consumes a constant share of wealth, $c_{it} = \rho w_{it}$, and chooses

$$\theta_{it} = \min \left\{ \vartheta, \frac{\mu_{it}^R}{(\sigma_{it}^R)^2} \right\}$$

Special country’s assets. The special country has a measure $\hat{q}$ of trees that are pooled together in a fund. The random components of their yields wash out, so the total output over $dt$ in the special country is $\hat{q}\nu dt$. Shares of these trees can only be traded as one, in a bundle with equal weights. I will refer to this fund as the special country’s tree for convenience.

The price of the special country’s tree is $\hat{p}_t$. The excess return is $d\hat{R}_t = (\nu dt + d\hat{p}_t)/\hat{p}_t - r_t dt$, idiosyncratic shocks washing out. The only agent trading this tree is the intermediary, whose holdings are denoted by $\hat{h}_t$. Since there is no risk, excess returns will be zero in equilibrium.

Intermediary with ambiguity aversion. I start by describing the problem of an intermediary who has access to a finite number of countries first. I then let the number of countries go to infinity to approximate the continuous limit. With the addition of the special country’s tree, the evolution of the intermediary’s wealth becomes

$$d\hat{w}_t = (r_t \hat{w}_t - \hat{c}_t)dt + \sum_i \hat{\theta}_{it} \hat{w}_t dR_{it} + \hat{\theta}_t \hat{w}_t d\hat{R}_t + \frac{\hat{w}_t}{\hat{w}_t} \cdot \hat{\lambda} w_t dt - \frac{\hat{w}_t}{\hat{w}_t} \cdot \hat{\lambda} \hat{w}_t dt$$

Here $\hat{\theta}_t$ is the portfolio share allocated to the special country’s tree.

The intermediary is unsure about the right probability measure for $dZ_{it}$, the random component of dividends in every $i$. To account for possible misspecification, the intermediary considers other probability measures $Q_i$ under which the process $\{Z_{it}\}_{t\geq0}$ given by $d\tilde{Z}_{it} = dZ_{it} + \xi_{it} dt$ is a Brownian motion instead of $\{Z_{it}\}_{t\geq0}$. The adapted sequences $\{\xi_{it}\}_{t\geq0}$ index these alternative measures $Q_i$. The evolution of an individual intermediary’s net worth can be rewritten as

$$d\hat{w}_t = (r_t \hat{w}_t - \hat{c}_t)dt + \sum_i \hat{\theta}_{it} \hat{w}_t ((\mu_{it}^R - \sigma_{it}^R \xi_{it})dt + \sigma_{it}^R d\tilde{Z}_{it}) + \hat{\theta}_t \hat{w}_t d\hat{R}_t + \frac{\hat{w}_t}{\hat{w}_t} (\lambda w_t - \hat{\lambda} \hat{w}_t) dt$$

(5)
Each of the alternative measures $Q_i$ is associated with a likelihood ratio $M_{it}$ relative to the original measure. These likelihood ratios are equal to 1 at $t = 0$ and evolve as

$$dM_{it} = -\xi_{it} M_{it} dZ_{it}$$  \hspace{1cm} (6)$$

The intermediary would like to consider scenarios with heavy losses, finding corrections $\xi_{it}$ that minimize its payoff. Discipline is provided by a penalty that keeps the intermediary from deviating too much from the baseline measure. The penalty function per unit of time for every $i$ is proportional to the expected value of $\eta(w_{is}) dm_{it}$, where $dm_{it}$ is the increment of the log-likelihood ratio $m_{it} = \log(M_{it})$, and $\eta(\cdot)$ is a non-decreasing (perhaps, constant) function of country $i$’s wealth. This allows for different levels of caution when assessing rich and poor countries. I add this to better approximate the distribution of external assets and liabilities.

The problem of an individual intermediary is

$$\max_{\{\hat{\epsilon}_s, \hat{\theta}_s\}_{s \geq t}} \inf_{Q \in \mathcal{Q}} \mathbb{E}_t^Q \left[ \rho \int_t^\infty e^{\hat{\rho}(s-t)} \log(\hat{c}_s) ds + \frac{1}{2} \sum_i \int_t^\infty e^{\hat{\rho}(s-t)} \hat{\gamma}_s \eta(w_{is}) dm_{is} \right]$$

subject to equation (5). Here $\mathcal{Q}$ is the set of alternative measures that can be represented by equation (6) and $\{\hat{\gamma}_t\}_{t \geq 0}$ is an adapted sequence of cost parameters.

The intermediary’s behavior can be described as looking at value-at-risk measures since it considers adverse scenarios. The difference relative to imposing a value-at-risk constraint directly is that cautious behavior here derives from preferences rather than regulatory constraints. Declines in risk-taking capacity can be ascribed to shifts in attitude to risk rather than tightening regulations.

The cost parameter $\hat{\gamma}_t$ captures appetites for risk since it determines how far the intermediary is willing to go with alternative adverse scenarios. A low $\hat{\gamma}_t$ means low costs of considering models with large potential losses, making risky assets less attractive. Unlimited capacity is nested as $\hat{\gamma}_t = \infty$, which leads the intermediary to set $dm_{it} = 0$ and stick to the baseline probability measure. In this case, the intermediary takes advantage of a perfectly diversified international portfolio and absorbs all idiosyncratic risk globally.

The intermediary solves the minimization problem first, choosing an alternative measure for every country $i$ and their product measure $Q$ to account for losses suggested by models in the admissible set $\mathcal{Q}$. It then solves the usual maximization problem for given model adjustments, choosing consumption and portfolio. In general, $\hat{\gamma}_t$ could be varying over time, generating temporary episodes of low risk-taking capacity.

The increment of the log-likelihood ratio $dm_{it}$ can be rewritten as

$$dm_{it} = -\xi_{it} dZ_{it} - \frac{1}{2} \xi_{it}^2 dt$$
Since \( dZ_{it} = d\tilde{Z}_{it} - \xi_{it}dt \), where \( d\tilde{Z}_{it} \) is a standard Brownian increment under \( Q_i \), the expectation of this under \( Q_i \) is \( E^Q_t[dm_{it}] = \xi_{it}^2 dt/2 \). The problem transforms into

\[
\max_{\{\hat{c}_s, \hat{\theta}_{s}, \hat{\theta}_{s}\}_{s \geq t}} \inf_{\{\xi_{s}\}_{s \geq t}} E^Q_t[\xi_{s}] = \int_t^\infty e^{\hat{\theta}(s-t)} \left( \hat{\gamma}_s \log(\hat{c}_s) + \frac{\hat{\gamma}_s}{2} \sum_i \eta(w_{it}) \xi_{is}^2 \right) ds
\]

subject to equation (5). This formulation acknowledges that the choice of measure \( Q \in Q \) is equivalent to selecting drift corrections \( \xi_{it} = \{\xi_{it}\} \). Importantly, alternative models are chosen separately for all countries, and the intermediary thinks that \( d\tilde{Z}_{it} \) are independent across \( i \).

Fix the number of regular countries at \( n \). Consumption of the intermediary is \( \hat{c}_t = \hat{\rho}\hat{w}_t \), and portfolio weights and drift correction for each country \( i \) are

\[
\hat{\rho}^{(n)}_it = \frac{\hat{\gamma}_t \eta(w_{it})}{1 + \hat{\gamma}_t \eta(w_{it})} \cdot \frac{\mu^{R}_{it}}{(\sigma^{R}_{it})^2} \\
\xi^{(n)}_{it} = \frac{1}{\hat{\gamma}_t \eta(w_{it})} \cdot \hat{\theta}_{it}^{(n)} \sigma^{R}_{it} = \frac{1}{1 + \hat{\gamma}_t \eta(w_{it})} \cdot \frac{\mu^{R}_{it}}{(\sigma^{R}_{it})^2}
\]

The intermediary’s portfolio weight of each risky asset is proportional to the mean-variance ratio. It also increases in the risk-taking capacity \( \hat{\gamma}_t \) and the country’s weight \( \eta(w_{it}) \). Whenever \( \hat{\gamma}_t \) is finite, ambiguity aversion attenuates portfolio weights, as the multiplier before the mean-variance ratio is between 0 and 1. The drift correction \( \xi^{(n)}_{it} \) is proportional to the Sharpe ratio, meaning that the intermediary takes a more cautious view of high-yielding countries.

To take the continuous limit, I let the number of countries \( n \) go to infinity. Payoffs in the limit have to include integrals over \( i \in [0, 1] \), and portfolio weights \( \hat{\theta}_{it} \) in the limit become a density:

\[ \hat{\theta}_{it} = \lim_{n \to \infty} n\hat{\theta}^{(n)}_{it} \]

To ensure that this limit exists, I let the risk-taking capacity \( \hat{\gamma}_t \) decrease as \( n \) diverges: \( \hat{\gamma}_t = \gamma_t/n \). This double limit of portfolio weights is

\[ \hat{\theta}_it = \gamma_t \eta(w_{it}) \cdot \frac{\mu^{R}_{it}}{(\sigma^{R}_{it})^2} \quad (7) \]

Why does risk-taking capacity have to go to zero as the number of countries grows? If the intermediary’s aversion to uncertainty does not rise as it gets access to a continuum of uncorrelated returns, it will take infinite positions as the law of large numbers wipes out all the risk. The limiting density in equation (7) does not exist unless \( \hat{\gamma}_t \) decreases at least as fast as \( \gamma_t/n \).

Another way to look at it is to account for total payoffs. Increasing \( n \) indefinitely gives the intermediary access to more and more uncorrelated assets, so without a commensurate rise in aversion to uncertainty the intermediary’s portfolio would blow up. It would borrow and invest
without an upper bound, and its wealth would not have well-defined dynamics in the limit.

The drift corrections approach the Sharpe ratio:

$$\xi_{it} = \lim_{n \to \infty} \xi^{(n)}_{it} = \frac{\mu^R_{it}}{\sigma^R_{it}}$$

Finally, the wealth of the special country in the limit follows

$$d\hat{w}_t = (r_t\hat{w}_t - \hat{c}_t)dt + \int_0^1 \hat{\theta}_t \hat{w}_t dR_{it} di + \hat{\theta}_t \hat{w}_t d\hat{R}_t + (\lambda w_t - \hat{\lambda} \hat{w}_t)dt$$

Borovička et al. (2023) similarly take a double limit to study aversion to ambiguity with recursive preferences. In their case, uncertainty vanishes at the same speed as the aversion to ambiguity increases, delivering a tractable limit.

Appendix E.1 reverses the order and poses the problem with a continuum of assets instead of solving a finite-country one and taking the limits of the solutions. The results are the same. Solving the finite-country problem first has a technical advantage: alternative measures chosen by the intermediary are absolutely continuous with respect to the true measure. With a continuum of countries, this does not hold, as all aggregates become deterministic and measures degenerate.

Ilut and Saijo (2021) use the same continuous limit in a model with a large portfolio of firms to generate endogenous movements in confidence that respond to aggregates. They explain the effect of idiosyncratic uncertainty on an ambiguity-averse decision-maker and relate it to work on laws of large numbers by Marinacci (1999) and Epstein and Schneider (2003).

Discussion. Two elements of the model are technical: migration between countries and intermediary’s weights $\eta(w_{it})$ on country-specific ambiguity. Migration enforces stationarity and does not affect consumption or portfolio decisions. I could use variable discount rates instead:

$$\rho(w_{it}, \hat{w}_t) = \rho + \lambda - \hat{\lambda} \hat{w}_t / w_{it}$$
$$\hat{\rho}(\hat{w}_t, w_{it}) = \hat{\rho} + \hat{\lambda} - \lambda w_{it} / \hat{w}_t$$

This would change consumption but not portfolio choice or wealth dynamics. Importantly, aggregate consumption given the distribution of wealth would not change either.

The weights $\eta(w_{it})$ make the steady-state distribution of external assets and liabilities better approximate the data. If $\eta(\cdot)$ is increasing, the intermediary is less concerned about ambiguity when it comes to richer countries, so the penalty for choosing alternative measures is higher for high $w_{it}$. Allowing for country-specific ambiguity captures some variation in investors’ perceptions of countries that go beyond observable returns. Through $\eta(w_{it})$, fluctuations in $w_{it}$ change the intermediary’s attitude to $i$’s assets given its risk-return profile. Hassan et al. (2021) provide evidence for dynamically changing perception of country-specific risk that affects investor preferences.
4 Equilibrium

This section defines equilibrium and describes the steady state and calibration. The equilibrium processes must satisfy four types of market clearing conditions: for shares of regular country trees, shares of the special country tree, bonds, and consumption goods. Individual wealth of representative savers must also agree with aggregate wealth in their respective countries.

**Definition 1.** Given a process \( \{\gamma_t\}_{t \geq 0} \), an equilibrium is a collection of price processes \( \{r_t, \{p_i\}, \hat{p}_t\}_{t \geq 0} \), wealth processes \( \{\{w_{it}\}, \{\hat{w}_{it}\}\}_{t \geq 0} \), consumption processes \( \{\{c_{it}\}, \hat{c}_t\}_{t \geq 0} \), and processes for asset holdings \( \{\{h_{it}\}, \{\hat{h}_{it}\}, \{b_{it}\}, \hat{b}_t, \hat{h}_t\}_{t \geq 0} \) such that all agents optimize and

- aggregate wealth process agrees with individual wealth: \( w_{it} = \hat{w}_{it} \) for all \( i \) and \( \hat{w}_t = \hat{\hat{w}}_t \)
- markets for regular country trees clear: \( h_{it} + \hat{h}_{it} = 1 \) for all \( i \in [0, 1] \)
- deposit market clears: \( \int b_{it} di = b_t \)
- market for the special country tree clears: \( \hat{h}_t = \hat{q} \)
- market for consumption goods clears: \( \int c_{it} di + \hat{c}_t = (1 + \hat{q})\nu \)

The last market clearing condition is automatically satisfied once all other market clearing conditions and budget constraints hold.

I drop the subscripts and refer to countries using their current wealth \( w \). This step could not be done before solving the intermediary’s problem because countries with different identities provide independent returns and have to be accounted for separately, even if their local dynamics are the same. But now, with portfolio choice given by equation (7), I can work directly with prices \( p(w, t) \) and portfolio shares \( \theta(w, t) \) and \( \hat{\theta}(w, t) \) that map into holdings \( h(w, t) \) and \( \hat{h}(w, t) \).

Rewriting the market clearing conditions for each regular country,

\[
\mu_R(w, t) = \sigma_R(w, t)^2 \cdot \max \left\{ \frac{p(w, t)}{\varphi(t)\eta(w) + w}, \frac{p(w, t) - \hat{\theta}w}{\varphi(t)\eta(w)} \right\}
\]  

(8)

This equation shows how returns are determined by available cash in the market given by local wealth \( w \) and intermediary’s demand \( \varphi(t)\eta(w) \), where the global factor \( \varphi(t) = \gamma(t)\hat{w}(t) \) is common to all markets, as in Section 2.

The max operator here shows that the local savers can be constrained or unconstrained in their portfolio choice. When the constraint is slack, the price of risk is given by the ratio of the total supply of assets \( p(w, t) \cdot 1 \) divided by the total demand \( \varphi(t)\eta(w) + w \). Both local and foreign investors are marginal. The elasticity of excess returns to the global factor \( \varphi(t) \) depends on the country’s wealth. In countries with a large \( w \), this elasticity approaches zero. Local savers can absorb all fluctuations in foreign demand without drastic movements in required returns. In poor
countries, local savers can do it less effectively, and the elasticity approaches $-1$ as $w \to 0$. This case is well described by the simple model of Section 2.

When the constraint binds for local savers, only the intermediary is marginal, so the price of risk is the residual supply $p(w, t) - \theta w$ divided by its demand $\varphi(t)\eta(w)$. This case is new relative to Section 2. The intermediary is the only marginal investor in these countries, and the elasticity of excess returns to $\varphi(t)$ is $-1$. Domestic investors cannot absorb any shifts in foreign demand, so they pass through to required returns one for one.

![Diagram](a) Constrained savers

![Diagram](b) Unconstrained savers

Figure 4: Supply and demand for country $i$’s trees as a function of the mean-variance ratio $\frac{\mu_R}{\sigma^2_R}$ for fixed $w$ and $p$. Supply is vertical. Demand $\hat{h}$ from the intermediary in red, $h$ from the local savers in blue. The total demand is a horizontal sum of the two. Local savers are constrained on panel (a) and unconstrained on panel (b). Dashed lines show shifted curves after foreign demand is partially withdrawn. Equilibria move from the black to the white dots.

A constrained country is illustrated on panel (a) of Figure 4. The red line depicts demand from the intermediary, local demand is in blue, and their horizontal sum in black is the overall demand. This line has a kink where the mean-variance ratio becomes so high that local savers hit their portfolio constraint. The supply line is vertical, and the supply-demand intersection is in the region where domestic demand is fully inelastic.

If a negative shock to $\varphi(t)$ leads to withdrawal of foreign demand, total demand shifts left. The new supply-demand intersection is at a higher mean-variance ratio. The blue line is vertical at this point, so local investors cannot increase their holdings. Since there is nobody to sell to, the intermediary has to accept the old quantities, and excess returns adjust to convince them to.

A more elastic case is illustrated on panel (a) of Figure 4. The fall in foreign demand still leads to an increase in required excess returns, but this time local savers are unconstrained and can compensate for capital flight. There is trade. They increase their holdings in response to wider spreads, and excess returns do not move as much.
The extent to which trades can insulate prices from the shock to $\varphi(t)$ depends on $w$, which in the picture maps into the slope of the blue line left of the kink. Large $w$ means a low slope, with a horizontal line in the limit or $w \to \infty$. Excess returns do not move at all in this case. Small $w$ makes the blue line closer to vertical. Poor unconstrained countries behave like constrained ones.

**General equilibrium.** How far is Figure 4 from general equilibrium? First, higher promised returns come from future price growth, which requires asset prices $p(w, t)$ to fall in equilibrium. This revalues portfolios and impacts wealth $w$ and $\dot{w}$. Consumption and interest rates respond to changes in wealth, which further revalues assets, including the safe asset issued in the special country that is not affected by $\varphi(t)$ in the first place.

Capital flows offer another general equilibrium perspective. When local investors buy domestic assets from the intermediary, they run down their foreign holdings. Since all unconstrained countries do this simultaneously, a fall in $\varphi(t)$ leads to a wave of global retrenchment, which is reflected in the shrinking balance sheets of global intermediaries, who now raise less funding to finance their investments. This deleveraging affects short-term rates, changing prices and revaluing wealth.

The main insights on heterogeneity from Figure 4 survive, though. Constrained markets show very limited trading activity, and adjustment happens through prices. Unconstrained markets in sufficiently rich countries see large trading volumes and, because of that, limited price movements. Closing the model pins down levels of responses in addition to differences between countries that are visible on Figure 4 already.

To recover prices, define equilibrium drift and volatility functions $(\mu_w, \mu_p, \sigma_w, \sigma_p)$ as

$$dw = \mu_w(w, t)dt + \sigma_w(w, t)dZ$$
$$dp = \mu_p(w, t)dt + \sigma_p(w, t)dZ$$

Here $dZ$ are increments of the country-specific Brownian motions. Using the definition of returns,

$$\mu_R(w, t) = (\mu_p(w, t) + \nu)/p(w, t) - r(t)$$
$$\sigma_R(w, t) = (\sigma_p(w, t) + \sigma)/p(w, t)$$

Plugging this into market clearing and using Itô’s lemma leads to a partial differential equation for $p(w, t)$. A related partial differential equation determines the evolution of the regular country wealth distribution $G(w, t)$ with the associated density $g(w, t)$.

**Proposition 1.** The prices $p(w, t)$ and density $g(w, t)$ solve the following system:

$$r(t)p(w, t) - \partial_t p(w, t) = y(w, t) + \mu_w(w, t)\partial_w p(w, t) + \frac{1}{2}\sigma_w(w, t)^2\partial_{ww}p(w, t)$$
$$\partial_t g(w, t) = -\partial_w[\mu_w(w, t)g(w, t)] + \frac{1}{2}\partial_{ww}[\sigma_w(w, t)^2p(w, t)]$$

20
subject to suitable boundary conditions. The risk-adjusted payoff function $y(w, t)$ is given by

$$y(w, t) = \nu - \left( \frac{\sigma}{1 - \epsilon(w, t)\theta(w, t)} \right)^2 \max \left\{ \frac{1}{w + \varphi(t)\eta(w)}, \frac{1}{\varphi(t)\eta(w)} \left( 1 - \frac{\bar{\theta}w}{p(w, t)} \right) \right\}$$

where $\epsilon(w, t) = w/p(w, t) \cdot \partial_w p(w, t)$ is the wealth elasticity of price.

The price $p(w, t)$ solves a standard Kolmogorov backward equation akin to those describing value functions. The discount rate is $r(t)$, and the reward function $y(w, t)$ is the tree yield adjusted for risk. The wealth distribution solves a standard forward equation, and these two equations are coupled. The feedback loop between them goes through $r(t)$, which clears the global bond market and therefore depends on the distribution of wealth, and the global factor $\varphi(t)$, which includes $\hat{w}(t)$, the special country’s net worth that depends on the distribution of prices.

A slight complication in solving the coupled system is that the payoff function depends on $p(w, t)$ and its derivative in a non-linear way. On top of that, one needs to know $p(w, t)$ to compute the drift and volatility of wealth. This turns the problem posed by Proposition 1 into finding a fixed point. I describe my solution algorithm in Appendix H.

Steady state. Suppose $\gamma(t)$ is constant and the economy is in the steady state with a steady-state wealth distribution and price, return, and portfolio weight functions. Notation for these steady-state versions omits the time argument.

Relative to Section 2, there is a new source of heterogeneity between rich and poor countries. Namely, there is a threshold $\bar{w}$ such that the local portfolio constraint $\theta(w) \leq \bar{\theta}$ binds in countries with $w < \bar{w}$. In poor countries, prices are depressed by low wealth in the market. This renders expected returns high, so domestic investors want to allocate a high share of their portfolio to the tree and hit the limit $\theta$.

As a country grows rich, it outgrows the constraint. Tree price rises together with wealth, lowering expected returns and making the tree less attractive. In addition, the price is bounded from above by the price of the riskless asset, so in rich countries, even the whole tree would take up a small share of domestic portfolios. In the limit of infinite wealth, local risk does not contribute to wealth dynamics, and wealth simply drifts down because of consumption ($\rho > r$).

Portfolio constraint makes the elasticity of excess returns to foreign demand $\varphi(t)$ equal to $-1$ in a fraction of countries. In the world without the constraint, as described in Section 2, this extreme elasticity is only present in the limit $w \to 0$. Introducing $\bar{\theta}$ spreads this behavior to all countries with $w < \bar{w}$. In unconstrained countries, he elasticity of excess returns to $\varphi(t)$ still increases in wealth and approaches zero when $w \to \infty$, as in Section 2.

Calibration. Table 1 presents the steady-state targets and model fit. I choose the model parameters to approximate the following moments. First, I designate the US as the special country and target US wealth share of 32.3% from Credit Suisse (2022) and US share of GDP of 25.4% from the World Bank data. Second, Gourinchas and Rey (2022) estimate that the US gets an annual

return of 2-3 percent on its external position. Third, Adler and Garcia-Macia (2018) estimate that emerging markets earn a 2.3pp lower real return on NFA compared to advanced economies. Finally, I make the model reproduce some moments of the empirical distribution of external assets relative to external liabilities. See Appendix G for details.

I further normalize average output $\nu$ and set $\hat{\lambda}$ to a value that induces zero net migration flows in the steady state. The parameters are $(\rho, \hat{\rho}, \lambda, \hat{\lambda}, \nu, \bar{\theta}, \sigma, \gamma, \hat{q}, \zeta)$, where $\zeta$ sets the intermediary’s weights: $\eta(w) = \zeta + (1 - \zeta)w$.

</table>

This affine specification has two properties. First, at $w \to 0$ it pans out to a constant, so the total demand for assets is bounded away from zero even in countries with vanishing wealth. These
countries are taken over by the intermediary, and the prices of their trees are bounded away from zero. Second, at $w \to \infty$ the intermediary’s demand is proportional to that of the local investors, so the trees are not completely taken over by domestic agents even as they become infinitely rich. This prevents the rich countries from having to hold the entire supply of their risky assets, in which case fluctuations in foreign demand would mechanically have very little effect.

The portfolio constraint parameter $\bar{\theta} = 0.71$ means that not only are regular countries unable to borrow, but they also must hold some riskless debt. This can be associated with regulatory mandates on investment vehicles. The share of unconstrained countries in the steady state is about 12%, which is close to the number of advanced economies in the world.

5 Financial and Real Shocks

This section illustrates a shock to risk-taking capacity $\gamma$ in the full model and discusses its general equilibrium implications in detail. I then compare this financial shock to a real shock that exogenously hits output and explain what features of aggregate data these two shocks map to.

**Shock to risk-taking capacity.** For illustration, suppose the economy is at the steady state during $t < 0$. At $t = 0$, there is an unanticipated shock to future path of $\gamma$:

$$
\gamma(t) = \gamma - \Delta \gamma e^{-\mu \gamma t} 1 \{t \geq 0\}
$$

I set the persistence parameter $\mu_\gamma = 0.24$ and the size of the shock $\epsilon_\gamma$ at 7.9% of the steady-state value of $\gamma$ in accordance with my estimation results from Section 6.

The shock to $\gamma(t)$ has an immediate effect on the global factor $\varphi(t) = \gamma(t) \hat{w}(t)$. The intermediary loses its appetite for risky assets and withdraws demand from all markets in regular countries. Expected excess returns rise. Since dividends are constant, these expected returns come from the initial fall in prices $p(w, t)$ and a positive drift as they gradually recover.

As investors lose money on risky assets, they feel poorer and want to consume less. But output is fixed, so the interest rate $r(t)$ has to fall to convince them to consume the old amount on aggregate. This revalues the special country’s tree: $\hat{p}(t)$ increases on impact. The fall in the intermediary’s risk-taking capacity thus generates a fall in the global interest rate and an appreciation of the riskless tree. Other assets are revalued, too, so the fall in $r(t)$ limits the overall fall in prices.

Figure 5 shows the responses of $r(t)$, $\hat{p}(t)$, and the average risky asset price $p(w, t)$. In addition to the average, panel (c) has the responses of prices at the 5-th and 95-th percentiles of the wealth distribution. They are different and even have the opposite signs. At the 95-th percentile, the tree gains value on impact, so its response is closer to that of the safe asset.

Figure 6 shows the cross-section of price and flow responses on impact. Panel (a) decomposes the response of prices into parts that come from the falling interest rate $r(t)$ and from the falling
foreign demand $\varphi(t)$. The effect of $\varphi(t)$ is only visible in the poorer part of the distribution. This is because, as panel (b) shows, domestic investors in rich countries retrench and compensate for the intermediary leaving. In poor countries, there are no flows, and prices absorb the shock.

Risky assets issued by rich countries thus endogenously behave as a good substitute for safe assets since they react positively to falling risk-taking capacity. Since retrenchment fully neutralizes the fall in foreign demand, these assets only react to $r(t)$. In the limit of $w \to \infty$, excess returns stay at zero, while absolute returns fall, leading to appreciation.

The safe asset, which is the special country’s tree, appreciates as well. In fact, the increase in its price $\hat{p}(t)$ is enough to increase the special country’s wealth $\hat{w}(t)$ on impact. This is consistent with the results in Dahlquist et al. (2022) and Jiang et al. (2022). The special country loses money on its foreign holdings but ends up increasing its wealth share.

Figure 5: Impulse responses of prices. Panel (a): global interest rate $r(t)$, percentage points. Panel (b): safe asset price $\hat{p}(t)$, percent of the steady-state value. Panel (c), solid line: average risky asset price $p(w, t)$, percent of the steady-state average. Dashed lines: responses of the prices at the 5-th percentile of the wealth distribution (in green) and at the 95-th percentile (in purple).

Figure 6: Cross-section of the changes in risky asset prices and domestic asset holdings on impact. Panel (a): percentage change in $p(w, t)$ relative to the steady state decomposed into the effect of interest rate $r(t)$ and foreign demand $\varphi(t)$. Panel (b): changes in tree holdings by domestic investors $h(w, t)$ as a percentage of the total supply. Steady-state distribution in the background.
What would happen without the constraint $\theta(w, t) \leq \bar{\theta}$? This case is considered in Section 2. More investors would buy domestic assets from the intermediary on impact. Of course, at the lower end of the distribution they cannot buy much, so prices would still have to adjust instead of quantities around $w = 0$. But aggregate effects would be quantitatively different: the fall in the interest rate required to prop up the prices and induce consumption would be less dramatic.

Importantly, without the constraint, some countries would borrow from the intermediary to buy assets, so there would be a rise in lending to poorer countries during global downturns. These countries would be issuing riskless debt to the intermediary to fund purchases of their risky assets. In my calibration, $\bar{\theta} = 0.71$ means that regular countries cannot borrow at all, and there is no spike in lending during busts.

**Distributional impact.** What do risky assets issued by different countries contribute to gains and losses of the global intermediary’s portfolio? And how are gains and losses distributed among investors in regular countries? Figure 7 shows them in cross-section, measured in percent of global GDP and weighted by the steady-state density so that they can be integrated directly to compute the totals. Table 3 aggregates gains and losses into those made by the intermediary on the safe assets and risky assets from countries that are initially constrained and unconstrained. Constrained countries have low wealth, so they map into emerging markets. Table 3 also aggregates the impact of the shock on the wealth of local investors.

Two things stand out. First, total wealth revaluation is close to zero. Because the elasticity of intertemporal substitution is equal to one, it always holds that

$$\int \rho wdG(w, t) + \hat{\rho} \hat{w}(t) = \nu(1 + \hat{q})$$

The shock to risk-taking capacity $\gamma(t)$ does not affect output. This means that the interest rate in general equilibrium will adjust to revalue assets enough to keep the weighted sum of global wealth on the left-hand side of this equation constant. An implication is that the intermediary’s wealth and that of the rest of the world cannot go down at the same time, and there has to be
redistribution with an approximately zero sum. If \( \rho = \hat{\rho} \), it is exactly zero-sum.

Second, there is substantial heterogeneity. Losses are concentrated in poorer countries. In contrast, risky assets issued in rich countries endogenously behave as almost safe due to retrenchment. At the same time, the intermediary shares in the losses in poor countries more than in the gains that rich countries make. This is because the intermediary’s portfolio is skewed towards high-yielding emerging markets.

Losses on risky assets in regular countries translate into a fall in the special country’s net foreign asset position. Thus, this country makes a wealth transfer to the rest of the world by absorbing part of their losses, consistent with observations in Gourinchas and Rey (2022). On the other hand, the intermediary’s exposure to the safe asset and risky assets from rich countries limits its losses, keeps its net worth afloat, and makes its wealth share increase on impact. Rich countries contribute to stabilizing the intermediary’s net worth \( \hat{w}(t) \) and, through that, help arrest the fall in \( \varphi(t) = \gamma(t)\hat{w}(t) \). The upshot is that rich countries partly insure the global intermediary, which in turn partly insures the poor countries.

**(a) Domest...**

Figure 8: Panel (a): holdings of domestic assets by local investors in percent of total supply (difference relative to the steady state). Solid line for the change on impact, dashed for the expected change one quarter out, dotted for the expected change one year out. Panel (b): changes in components of expected wealth accumulation over the first quarter. Changes in prices in red, changes in interest income in blue, changes in dividends in green. Horizontal axis corresponds to wealth at \( t = 0 \), right before the shock hits.

**Adjustment in regular countries.** How do regular countries adjust? Panel (a) on Figure 8 shows the expected changes in holdings of domestic assets relative to the steady state. Expectations here are taken with respect to idiosyncratic shocks, and the horizontal axis corresponds to wealth at \( t = 0 \). See details in Appendix I.

Investors in rich countries retrench on impact and buy about 1% of the total supply of domestic assets. They then gradually sell them back in transition. These transactions, of course, are the other side of the intermediary’s asset purchases.

Panel (b) decomposes expected wealth accumulation in regular countries over the first quarter.
Changes in asset prices are positive for poor countries and negative for rich ones as the world reverts back to normal. Interest income declines for everyone, but disproportionately so for rich investors. Dividend income increases for rich investors since they retrench and have more risky assets in portfolios right after the shock. To finance consumption, investors from rich countries have to sell assets since their interest income declines more than their dividend income rises.

The world becomes more unequal in terms of wealth and in terms of spreads after the shock. Realized returns right after the shock are negative in poorer countries and close to zero in richer countries. This is consistent with the results in Chari et al. (2020), who show that the left tail of the return distribution moves more than the right tail during risk-off episodes. The distribution of required returns in the model also becomes more dispersed and skewed.

**Shocks to output.** I now describe another type of shock: a persistent decline in output. I hit the economy separately with two unanticipated shocks, one to output in regular countries and one to the special country’s output. They both have the following shape:

\[ \nu(t) = \nu - \Delta \nu e^{-\mu \nu t} \mathbb{1}\{t \geq 0\} \]

I set the size of the shock $\Delta \nu$ to 2.2% of the steady-state value $\nu$ and persistence parameter to $\mu = 0.78$ in accordance with my estimation results from Section 6.

The aggregate effects of these two shocks are qualitatively similar. Output falls on impact, so the interest rate has to rise to make agents consume less. Asset prices fall because of lower future dividends, and the rising interest rate depresses them even further. Magnitudes differ by about three times: the output share of the special country is approximately one-quarter of the total.

The falling asset prices revalue everyone’s wealth. In particular, the intermediary’s net worth $\hat{w}(t)$ takes a hit, which affects the global factor $\varphi(t) = \gamma(t) \hat{w}(t)$. From the perspective of the equilibrium condition on excess returns in equation (8), it looks like a fall in the intermediary’s risk-taking capacity. Importantly, this happens in both cases. It is natural to expect losses to be
distributed between both regular country investors and the special country when the shock hits the former: both local investors and the global intermediary hold risky assets. The shock to the special country, on the other hand, hits dividends on the safe asset, which is only held by the intermediary. The fact that it spreads to regular countries through \( \varphi(t) \) and \( r(t) \) reflects strong contagion forces.

Figure 9 shows the cross-section of impact changes in asset prices. Unlike with a shock to risk-taking capacity \( \gamma(t) \), prices fall everywhere because the interest rate rises. Panel (a) shows a rough decomposition of the impact effect into parts that come from a jump in \( r(t) \), a fall in \( \varphi(t) \), and a fall in \( \nu(t) \). The interest rates drive asset prices in the right tail of the wealth distribution. In poor countries, prices respond to foreign demand \( \varphi(t) \) and discounted future cash flows more. The decomposition is not exactly additive since the price function is highly non-linear.

Empirically, US shocks are an important driver of global dynamics. Boehm and Kroner (2023) show that news about the US economy has strong effects on risky asset prices globally. Miranda-Agrippino and Rey (2020) provide evidence for the global impact of contractionary monetary policy in the US. Kalemli-Özcan (2019) documents spillovers of US monetary policy that are particularly large for emerging markets. My model does not have a nominal dimension and monetary policy, but the real projection of a richer nominal model could generate spillovers from the special country to the rest of the world through the same mechanism.

**Differences between shocks to \( \gamma \) and \( \nu \).** Prices react to financial and real shocks in different ways. After a negative shock to output, all prices fall, showing strong procyclicality with respect to \( \nu \). After a negative shock to risk-taking capacity, prices in poor countries fall, and those in rich countries rise. The former are procyclical with respect to \( \gamma \), and the latter countercyclical. Special country’s tree shows the same pattern as those in rich countries.

Another contrast between these shocks to \( \nu \) and \( \gamma \) is capital flows on impact. Output shocks generate flows of similar magnitudes across countries. The reason is that they do not raise disagreement on the risk properties of assets. The absolute risk aversion of the intermediary is \( \gamma(t)\hat{w}(t)\eta(w) \), and that of the local investor is simply \( w \). Since \( \gamma \) is constant, they only change relative to each other to the extent that \( w \) and \( \hat{w}(t) \) change by different amounts. Hence, trades are driven by differences in wealth revaluation between local agents and intermediaries. These differences are similar across countries.

With a shock to \( \gamma \), this is not the case: the fall in \( \gamma \) dominates movements in wealth, so the shock opens a large gap between absolute risk aversion coefficients, generating trades. Capital flows are strongly procyclical in rich countries and less so in poor ones.

I next estimate the model using data on asset returns and capital flows. Output shocks are essential, since data show large swings in aggregate returns. The model will attribute most of them to movements in \( \nu \). Since the effects of output shocks are similar when they originate in the special country and in the rest of the world, I shock \( \nu \) in all countries at the same time.
6 Estimation

To estimate the model, I work with its first-order approximation. Shocks to $\gamma$ and $\nu$ drive the dynamics. I use the following processes for their deviations from the steady state:

$$
\begin{align*}
    d\tilde{\gamma}(t) &= -\mu_\gamma \tilde{\gamma}(t) dt + \sigma_\gamma \cdot dW(t) \\
    d\tilde{\nu}(t) &= -\mu_\nu \tilde{\nu}(t) dt + \sigma_\nu \cdot dW(t)
\end{align*}
$$

Here $\tilde{\gamma}(t) = \gamma(t) - \gamma$ and $\tilde{\nu}(t) = \nu(t) - \nu$ with $(\gamma, \nu)$ being the steady-state values. The shock increments $dW(t)$ are two-dimensional standard Brownian. Parameters $\mu_\gamma$ and $\mu_\nu$ govern persistence. Loadings $\sigma_\gamma$ and $\sigma_\nu$ are two-dimensional vectors. The first-order approximation of the model is around $\sigma_\gamma = \sigma_\nu = (0,0)$.

I work in the sequence space and compute sequence-space Jacobians. Take two sequences of deviations $\{\tilde{\gamma}(t)\}_{t \geq 0}$ and $\{\tilde{\nu}(t)\}_{t \geq 0}$ that become known at $t = 0$. Take also a sequence $\{z(w, t)\}_{t \geq 0}$. For any $t \geq 0$, the first-order deviation of $z(w, t)$ is

$$
\tilde{z}(w, t) = \int_0^\infty J_{z,\gamma}(w, t, \tau) \tilde{\gamma}(\tau) d\tau + \int_0^\infty J_{z,\nu}(w, t, \tau) \tilde{\nu}(\tau) d\tau
$$

Here $J_{z,\gamma}$ and $J_{z,\nu}$ are sequence-space Jacobians of $z$. They are defined for $t \geq 0$, $\tau \geq 0$, and all $w$. The fact the deviation sequences $\{\tilde{\gamma}(t), \tilde{\nu}(t)\}_{t \geq 0}$ become known at $t = 0$ is important. Shocks $dW$ that will happen in the future cannot affect the economy now through the deviations they have not yet created. The time-varying function of wealth $z(w, t)$ can represent, for example, asset prices $p(w, t)$ or the probability density of wealth $g(w, t)$.

I find these sequence-space Jacobians by solving the linearized version of the coupled system of equations from Proposition 1. Appendix K shows the linearized system and explains the algorithm.

First-order deviations of aggregate sequences $\{x(t)\}_{t \geq 0}$ can be written as

$$
\tilde{x}(t) = \int_0^\infty J_{x,\gamma}(t, \tau) \tilde{\gamma}(\tau) d\tau + \int_0^\infty J_{x,\nu}(t, \tau) \tilde{\nu}(\tau) d\tau
$$

with $J_{x,\gamma}$ and $J_{x,\nu}$ being its sequence-space Jacobians.

Since these deviations are first-order, $\tilde{x}(t)$ additively subsumes the first-order reaction of $x(t)$ to all deviations in $\gamma$ and $\nu$ that became known prior to $t$. At any $s \leq t$, the shock $dW(s)$ reveals a new deviation in $\gamma$ and $\nu$ that has the following time profile: $\tilde{\gamma}(s + \tau) = e^{-\mu_\gamma \tau} \sigma_\gamma \cdot dW(s)$ and $\tilde{\nu}(s + \tau) = e^{-\mu_\nu \tau} \sigma_\nu \cdot dW(s)$ for all $\tau \geq 0$. The deviation $\tilde{x}(t)$ adds up responses to all these happening before $t$:

$$
\tilde{x}(t) = \int_{-\infty}^t \left( \int_0^\infty J_{x,\gamma}(t - s, \tau) e^{-\mu_\gamma \tau} d\tau \right) \sigma_\gamma \cdot dW(s) + \int_{-\infty}^t \left( \int_0^\infty J_{x,\nu}(t - s, \tau) e^{-\mu_\nu \tau} d\tau \right) \sigma_\nu \cdot dW(s)
$$
This can be rewritten as

\[
\tilde{x}(t) = \int_{-\infty}^{t} (\tilde{J}_{x,\gamma}(t - s; \mu_\gamma)\sigma_\gamma + \tilde{J}_{x,\nu}(t - s; \mu_\nu)\sigma_\nu) \cdot dW(s)
\]

Here the reduced Jacobians \(\tilde{J}_{x,\gamma}\) and \(\tilde{J}_{x,\nu}\) are

\[
\tilde{J}_{x,\gamma}(t; \mu_\gamma) = \int_{0}^{\infty} J_{x,\gamma}(t, \tau) e^{-\mu_\gamma \tau} d\tau
\]

\[
\tilde{J}_{x,\nu}(t; \mu_\nu) = \int_{0}^{\infty} J_{x,\nu}(t, \tau) e^{-\mu_\nu \tau} d\tau
\]

For estimation, a sample path of \(\tilde{x}(t)\) can be integrated from a simulated sequence of shocks \(dW\) given parameters. Jacobians \(J_{x,\gamma}\) and \(J_{x,\nu}\) only require knowing the steady state. Parameters that determine the steady state come from the calibration procedure explained in Section 4. To estimate the parameters of the processes for \(\gamma\) and \(\nu\), I use the method of simulated moments.

**Data.** I use two aggregates \(x(t)\): total outflows \(m(t)\) and average risky asset prices \(p(t)\) given by

\[
m(t) = \int (1 - \theta(w, t))wdG(w, t)
\]

\[
p(t) = \int p(w, t)dG(w, t)
\]

I compute their first-order deviations in the model and normalize them by the steady-state values. These quantities are denoted by \(\tilde{m}(t)\) and \(\tilde{p}(t)\).

To construct the data analog for outward flows, I take the Balance of Payments and International Investment Positions data from the IMF. For a country \(i\) in quarter \(t\), the quantity \(f_{it}^{\text{raw}}\) denotes net purchases of foreign assets. Following Forbes and Warnock (2012) and Forbes and Warnock (2021), I take a smooth version:

\[
f_{it} = \sum_{t-3}^{t} f_{it}^{\text{raw}} - \sum_{t-7}^{t-4} f_{it}^{\text{raw}}
\]

I restrict attention to portfolio debt, portfolio equity, and “other” assets (banking flows). The analog of \(\tilde{m}(t)\) is

\[
M(t) = \frac{\sum_i f_{it}}{\sum_i A_{i,t-1}}
\]

where \(A_{i,t-1}\) is the stock of these assets one quarter before in country \(i\). See Appendix B for details of data construction and sample statistics.

I construct the analog of \(\tilde{p}(t)\) from the MCSI asset price index that excludes the US. Denote
the quarterly version of this index by $Q_t$. The analog of $\tilde{p}(t)$ is quarterly returns smoothed over the four-quarter window: $P(t) = \sum_{t-3}^{t} Q_s/Q_{s-1}$.

Figure 10 shows the data. The sample is 85 quarters long, starting in Q4 of 2001, which is the first point at which I have more than 10 emerging markets in the sample for capital flows. I compute moments of these series and compare them to moments of simulated sequences, looking for a combination of parameters that minimizes a quadratic distance. Table 4 shows the targets.

Table 4: Targeted moments.

I estimate five parameters in total. The first two are persistence levels ($\mu_\gamma, \mu_\nu$). Both loading vectors are two-dimensional: $\sigma_\gamma = (\sigma_{\gamma 1}, \sigma_{\gamma 2})$ and $\sigma_\nu = (\sigma_{\nu 1}, \sigma_{\nu 2})$. I normalize $\sigma_{\nu 1} = 0$. The first dimension of the shock, $dW_1(t)$, only affects $\tilde{\gamma}(t)$, while $dW_2(t)$ hits both $\tilde{\gamma}(t)$ and $\tilde{\nu}(t)$. Increments $d\tilde{\gamma}(t)$ and $d\tilde{\nu}(t)$ are potentially correlated.

Table 5 shows estimated parameters. I estimate standard errors using parametric bootstrap. See Appendix G.2 for details.
Figure 11 shows the first-order responses of $\tilde{m}(t)$ and $\tilde{p}(t)$ to the standard paths of $\tilde{\gamma}_t$ and $\tilde{\nu}_t$:

$$\tilde{\gamma}(t) = |\sigma_{\gamma}|e^{-\mu_{\gamma}t} \cdot 1\{t \geq 0\}$$

$$\tilde{\nu}(t) = |\sigma_{\nu}|e^{-\mu_{\nu}t} \cdot 1\{t \geq 0\}$$

The shock to $\gamma$ affects outward flows more strongly than prices since prices in rich and poor countries move in opposite directions. The shock to $\nu$ affects prices more strongly, shifting all of them in the same direction. In aggregate data, the volatility of $P(t)$ and $M(t)$ is similar, so the model needs both shocks. In the next section, I analyze their contributions to the cyclicality of key quantities separately.

7 Quantitative Analysis

This section dissects the effect of financial and real shocks on global aggregates and on rich and poor countries separately. I start by showing that the model captures key differences between rich and poor countries along the cycle, even though I only use global sequences to estimate parameters of aggregate shocks.

Untargeted moments. I map rich countries in the model to advanced economies in the data. A natural threshold in the model is the level of wealth at which the portfolio constraint starts to bind in the steady state. I designate countries richer than this cutoff as advanced economies and those below as emerging markets.

Table 6 shows untargeted volatilities of outward flows and asset prices. The model captures two aspects of heterogeneity from the data. First, the volatility of outward flows as a share of assets is larger in advanced economies. In the model, this property derives naturally from the portfolio constraint that stops investors from poorer economies from reacting to global shocks. Second, asset prices are more volatile in emerging markets. The model generates the same pattern by allowing investors from rich economies to retrench and compensate for the shortfall of foreign demand without much higher risk premia.

The model overestimates the difference in the volatility of flows. This is because there is an artificially sharp change in behavior around the portfolio constraint. Redefining advanced economies and emerging markets so that some advanced economies are also constrained in the steady state partly alleviates this. The same applies to asset prices. The model definition of advanced economies overstates the difference in volatility, and designating some constrained countries as rich would make this less pronounced.

Table 7 shows correlations between the relative performance of rich and poor economies and aggregates. The correlation between \( \tilde{m}_t^{AE} - \tilde{m}_t^{EM} \), which is how much more outward investment rich countries do, and global outward lows \( \tilde{m}_t \) is positive in the data. This means, for example, that investors from rich countries more actively retrench in downturns. Adding this fact to that in Table 6 means that not only are outward flows more volatile in advanced economies, but they are also more closely timed to global shocks. The model reproduces this pattern, although it does not hit the correlation quantitatively.

The correlation of relative performance of assets \( \tilde{p}_t^{AE} - \tilde{p}_t^{EM} \) with aggregate flows \( \tilde{m}_t \) is negative. Advanced economies outperform emerging markets more in global downturns, which is when capital flows recede. In the model, a strong negative correlation is generated by more active retrenchment in rich countries insulating asset prices from foreign demand shocks. The last column confirms this, showing that advanced economies outperform emerging markets more when there is a deeper fall in their outward flows.

The converse of this is, of course, the better relative performance of emerging markets in global booms, which is when aggregate outward flows are on the rise. Advanced economies grow their external investment by more, and this reduction in domestic demand partly compensates for large inflows generated by intermediaries. In poor countries, domestic investors are constrained, so the reduction in the desired portfolio share of the domestic tree does not cause a reduction in the actual share. A rising foreign demand meets inelastic residual supply.
Financial and real shocks. Shocks to the intermediary’s risk-taking capacity and output shocks have the same implications for poor countries in the model: asset prices fall after a decrease in either of the two. In rich countries, asset prices load positively on $\nu$ but negatively on $\gamma$. The same happens in the special country. The interest rate responds positively to output and negatively to risk-taking capacity. Figure 12 shows these patterns using impulse responses obtained with sequence-space Jacobians.

Figure 12: First-order impulse responses of asset prices averaged across poor countries $p^{EM}$, asset prices averaged across rich countries $p^{AE}$, the special country’s price $\hat{p}$, and the interest rate $r$. Top row: shock to $\gamma$. Bottom row: shock to $\nu$.

Table 8 shows variance decomposition for first-order deviations of total outward flows $m_t$, the global average of asset prices $p_t$, and separately averaged asset prices in advanced economies and emerging markets $p_t^{AE}$ and $p_t^{EM}$. The last row shows the decomposition for $p_t^{AE} - p_t^{EM}$, which measures relative performance of assets in advanced economies compared to emerging markets.

Table 8: standard deviations of first-order responses. Responses measured in units of the respective steady-state values, except for the last row.
One observation is that output shocks contribute more to variance of both aggregate flows $m_t$ and average asset prices $p_t$. The model attributes a large share of variation in the data to $\nu$, so the picture would be incomplete without including it. Moreover, I estimate the shocks to have a positive correlation of 0.56, so output is often falling in times of low risk-taking capacity.

Another observation is that the relative contribution of shocks to risk-taking capacity to flows $m_t$ is larger than that to prices $p_t$. This is consistent with the fact that shocks to $\gamma$ are redistributive and do not destroy aggregate wealth. Financial shocks explain 24% of the variance in aggregate capital flows.

The model can explain around 55% of the variance in the $p_t^{AE} - p_t^{EM}$, the relative performance of assets in advanced economies compared to emerging markets. Financial shocks alone explain about a third of the total variance, and real shocks in isolation about 10%.

The relative performance of advanced economies is one quantity to which output shocks contribute less than the shock to risk-taking capacity. The reason is that advanced economies outperform emerging markets in downturns due to more active retrenchment, which is tightly connected to risk-taking capacity shocks. Output shocks do not generate differential retrenchment patterns, since flows in times of low output are mainly generated by domestic agents losing less wealth than intermediaries and becoming relatively richer, which leads to them taking over the tree. This happens in all countries, with little effect of size or the portfolio constraint.

**Cyclicality.** Since the two shocks move asset prices in advanced economies in opposite directions, it is natural to expect the cyclicality of prices to be different from that in emerging markets. To assess cyclicality, I use their correlation with aggregate outward flows $\tilde{m}_t$. The response of $\tilde{m}_t$ to both shocks is positive, and $\tilde{m}_t$ is a natural barometer of the global financial cycle. I compute the correlations in the full model and then shut down the shocks to $\gamma$ and $\nu$ separately to gauge their respective contributions.

Table 9: correlations of first-order responses with total outflows $\tilde{m}_t$

Table 9 shows the correlations. All prices are procyclical in the full model, and the interest rate is countercyclical: it rises in downturns. In emerging markets, correlation with $\tilde{m}_t$ is the highest, since both shocks to $\gamma$ and $\nu$ contribute positively. In advanced economies and in the special country, shocks to risk-taking capacity contribute negatively, which partly offsets positive co-
movement coming from shocks to output, and the overall correlation is lower. As a result, relative performance of assets in advanced economies compared to emerging markets is countercyclical.

Table 10 shows what this implies for the cyclicality of wealth. The correlation of wealth in advanced economies and the special country with $\tilde{m}_t$ is three times lower than that in emerging markets. This difference is coming from the shocks to risk-taking capacity that redistribute to rich countries in downturns, suppressing the volatility of their wealth.

Table 10: correlations of first-order responses with total outflows $\tilde{m}_t$

The shock to risk-taking capacity turns out to have a stabilizing impact in rich countries, especially since it is positively correlated with the output shock. In times of low output, the risk-taking capacity of global intermediaries is often low as well, which benefits rich countries since their propensity to retrench supports their asset prices in downturns.

**Limitations of the model.** The model is an exchange economy without differentiated goods, nominal rigidities, investment, policymakers, or within-country heterogeneity.

Adding differentiated goods and nominal rigidities can help incorporate the feedback between aggregate demand and output. I estimate a positive correlation between shocks to risk-taking capacity and output shocks. This suggests that a model with endogenous output could fit the data just as well if the output is occasionally demand-determined and risk-taking capacity shocks affect aggregate demand through asset prices, as described by Caballero and Simsek (2020b).

Nominal rigidities are important for monetary policy. Kalemli-Özcan (2019) shows that advanced economies and emerging markets are exposed to the US monetary policy in different ways. Their own policy responses are different too, as shown by De Leo et al. (2022) and Das et al. (2022). This heterogeneity could have aggregate implications.

The fact that in reality, all countries issue assets denominated in dollars as well as their local currency generates another contagion mechanism, as pointed out by Jiang et al. (2020). Tracking the distribution of countries and gross capital flows is important for studying these questions. However, the picture is incomplete without fluctuating exchange rates since exchange rates absorb non-trivial fractions of movements in risk premia and asset prices.

Investment and, more generally, endogenous supply of assets is necessary to model more realistic macro adjustment to short-run shocks and long-run growth. When the supply of assets is not fixed, gross flows matter for borrowing costs and have an important connection to the real economy. Adding these elements to the model can open the door to studying capital controls, industrial policy, and their external spillovers.
The data I use do not include reserves, which in reality play an important role in external adjustment. Reserves are deployed by social planners and do not only respond to risks and returns. I also do not consider capital control or financial repression policies. Local planners may turn out to create international externalities, posing a non-trivial problem for the global planner. Considering the local planner’s problem could be a useful next step, as well as thinking about a global planner that addresses possible coordination issues between local planners around the world.

8 Conclusion

I develop a model of the world economy with two tiers of heterogeneity between countries. The special country occupies the place of a global intermediary and issues safe assets. Regular countries issue risky assets and endogenously differ in wealth. The differences in wealth lead to different responses to global shocks that drive risk premia and capital flows.

In particular, when the intermediary’s risk-taking capacity decreases and it sells risky assets around the world, investors in rich countries retrench and support the prices of domestic assets. Poor countries do not have enough wealth and hit the constraint that prevents them from massively borrowing to replicate the response of rich countries with leverage. In their markets, prices adjust instead of quantities and drop sharply. The falling interest rate revalues assets, appreciating those issued by rich countries, which effectively makes them good substitutes for safe assets. The distributional impact is regressive, although rich countries insure the poor ones.

I find that real shocks are as important as financial shocks for the model to capture aggregate fluctuations in capital flows and asset prices. However, financial shocks are the main driver of the relative performance of assets in rich countries compared to those in poor ones. Asset prices in rich countries load negatively on the intermediary’s risk-taking capacity, and this makes their wealth less volatile and less cyclical.

References

Chernov, M., Haddad, V., and Itskhoki, O. (2023). What do financial markets say about the exchange rate?

A Two facts about capital flows

In this section, I establish the fact that outward flows from advanced economies are more strongly correlated with global aggregates, and their cyclical components are more volatile.

"Outflows" are net purchases of foreign assets by domestic investors. "Inflows" are net purchases of local assets by foreign investors. Both are "gross" flows, even though they can be negative. They do not have to add up to zero across countries, in contrast to net flows. I zoom in on outflows to focus on the role of domestic investors in shaping international heterogeneity.

The main point this section makes is that private outflows from advanced economies are more synchronized with the global financial cycle, both in terms of correlation and in terms of magnitude. Investors from advanced economies time their retrenchment to downturns more precisely and retrench more actively than those in emerging markets.

The data come from the Balance of Payments and International Investment Positions statistics provided by the IMF. I supplement these with GDP data from the World Bank. See Appendix A for details. Following the detrending procedure from Forbes and Warnock (2012) and Forbes and Warnock (2021), I construct the following variables:

\[ f_{it} = \sum_{s=t-3}^{s=t-4} FA_{i,s} - \sum_{s=t-7}^{s=t-4} FA_{i,s} \]  
(A.1)

Here \( t \) is a quarter, \( i \) is a country, and \( FA_{i,t} \) records net purchases of foreign assets by \( i \). Forbes and Warnock (2012) and Forbes and Warnock (2021) use similar measures to detect extreme capital flow episodes such as stops, surges, flight, and retrenchment. The position-adjusted version is

\[ \bar{f}_{it} = \sum_{s=t-3}^{s=t} \frac{FA_{i,s}}{A_{i,s-1}} - \sum_{s=t-7}^{s=t-4} \frac{FA_{i,s}}{A_{i,s-1}} \]  
(A.2)

Here \( A_{it} \) is the total stock of \( i \)'s external assets in quarter \( t \). Both \( FA_{it} \) and \( A_{it} \) are measured in dollars and exclude reserves and FDI. Of course, private outflows do not fully describe adjustment to shocks, since countries regularly deploy reserves, often at a large scale. These interventions and other operations not driven by profit maximization are beyond the scope of my paper.

Note that \( FA_{i,t} \) is different from the total change in position \( A_{i,t} - A_{i,t-1} \) because the latter includes valuation effects. The variables \( f_{it} \) and \( \bar{f}_{it} \) are constructed to account for trades, not price changes. Equation (A.1) calculates a de-trended and de-seasoned version of changes in assets due to trades and equation (A.2) calculates percentage changes due to trades.

To track the global cycle, I extract the principal component \( \phi_t \), which I call the outflow factor, from a balanced subpanel of \( f_{it} \) covering the last 20 years. I rescale all series in the panel to have the same volatility so that \( \phi_t \) is not mechanically driven by countries with the largest flows.
Figure A.1: Principal component $\phi_t$ of outflows $f_{it}$ and quarterly returns on MSCI ACWI smoothed over the four-quarter windows, both normalized to have zero mean and unit standard deviation.

Figure A.1 shows $\phi_t$ with returns on MSCI ACWI, a global index of asset prices with a broad international coverage. A large literature (see Miranda-Agrippino and Rey (2022) for a review) documents co-movement between capital flows and measures of global risk appetite. Outflows from countries that load more on $\phi_t$ should be more aligned with these measures and more closely follow the global cycle. These more exposed countries turn out to be advanced economies.

**Fact 1: outflows from advanced economies are more correlated with global factors.** The principal component $\phi_t$ of capital outflows explains more variation in outflows $f_{it}$ from advanced economies than from emerging markets. I measure this by computing $R^2$ of

$$f_{it} = \alpha_t + \beta_t \phi_t + \varepsilon_{it}$$

Figure A.2 shows results for individual countries in the sample. The average over advanced economies is 26% and that over emerging markets is 10%. Outflows from advanced economies are more tightly connected to global factors than those from emerging markets.

Figure A.2: Share of time-series variation in $f_{it}$ explained by $\phi_t$ for a given country $i$.

This means that outflows from advanced economies co-move with measures or risk appetites more closely since they are more tightly connected to $\phi_t$. Table 11 confirms this by showing
correlations between within-group averages and time series associated with the global financial cycle.

Table 11: Correlation between aggregate series and averages \(\{f_{t}^{AE}, f_{t}^{AE}, f_{t}^{EM}, f_{t}^{EM}\}\)

<table>

<td>0.00</td>
</tr>
</tbody>
</table>

Here the variables \(f_{t}^{AE}\) and \(\bar{f}_{t}^{AE}\) average \(f_{it}\) and \(\bar{f}_{it}\) over advanced economies, while \(f_{t}^{EM}\) and \(\bar{f}_{t}^{EM}\) average outflows from emerging markets. The asset price factor from Miranda-Agrippino and Rey (2020) is a dominant component that they extract from 858 series of risky asset prices around the world. The intermediary factor from He et al. (2017) traces the capital ratios of financial intermediaries, is highly cyclical, and explains variation in expected returns on large classes of assets. The treasury basis from Jiang et al. (2021) is a measure of convenience yield on short-term US treasury bonds that rises with demand for these safe assets.

The differences in correlations between advanced economies and emerging markets are noticeable in most cases and particularly salient when flows are measured relative to outstanding positions (the highlighted column). Outflows from advanced economies are more strongly synchronized with measures of global risk appetites. I next show that they are larger in magnitude.

Fact 2: cyclical component of outflows relative to outstanding positions is more volatile in advanced economies. Measuring magnitudes requires an adjustment for size. Flows relative to outstanding positions \(\bar{f}_{it}\) is a natural candidate. They show how much of their aggregate portfolio investors move during the cycle. To extract the cyclical component, I measure the group-specific loadings of \(\bar{f}_{it}\) on the dominant component in outward flows \(\phi_{t}\):

\[
\bar{f}_{it} = \alpha_{i} + \gamma\phi_{t} + \beta\{i \in AE\}\phi_{t} + \varepsilon_{it}
\]

The coefficient \(\beta\) measures the difference between the loadings of position-adjusted flows on the dominant factor between advanced economies and emerging markets. Table 12 shows that the loadings are larger in advanced economies. The quantitative interpretation is that investors from advanced economies repatriate 2.5% more of their external assets when the dominant component \(\phi_{t}\) is one standard deviation down.

Fact 1 shows that investors in advanced economies time their purchases of foreign assets to the global financial cycle. Fact 2 now additionally shows that they rebalance portfolios more actively, as measured by flows relative to outstanding positions. The same applies to busts: advanced
Table 12: the dependent variable $\bar{f}_{it}$ is expressed as percentage.

Economies retrench in crises and do it more actively than emerging markets.

Figure A.3 summarizes the patterns of synchronization in the two groups. Solid lines show the average components $\bar{f}_{it}^{AE}$ and $\bar{f}_{it}^{EM}$. This cross-sectional dispersion for every $t$ is shown by the shaded area. Position-adjusted outflows in advanced economies follow the outflow factor more closely on average and are less dispersed around it. Outflows are overall more volatile in emerging markets, but this is because idiosyncratic variation dominates. The average component in advanced economies is more volatile than that in emerging markets. I show this with a variance decomposition in Appendix B.

Figure A.3: Aggregate outflows from advanced economies and emerging markets relative to external assets. Black line: outflow factor $\phi_t$, rescaled for illustration. Solid line and shaded areas show cross-sectional averages and standard deviations of $\bar{f}_{it}$ for each quarter $t$.

Appendix B also shows that these results are stronger for GDP-adjusted flows. The reason is that advanced economies have more external assets relative to GDP, so flows as a share of GDP are more volatile in both aggregate and idiosyncratic components. Flows relative to positions are more informative because they quantify investor activity relative to their wealth. The fact that wealth is not equally comparable with output in all economies speaks to the economics of long-run asset accumulation. The fact that investors in advanced economies, on aggregate, move larger shares of their portfolio with the global financial cycle, is instead more informative about their demand for risky assets and the distribution of short-run demand elasticities. These observations motivate the model.
Additional details for empirical facts

I use IMF data on assets and liabilities from the International Investment Position dataset and financial accounts from the Balance of Payments dataset. I combine “portfolio investment” (both debt and equity) with “other investment”, which contains bank loans. The GDP data come from the World Bank.

Figure A.4: Number of countries in the sample. Left: acquisition of external assets and incurrence of external liabilities. Center: acquisition of assets and incurrence of liabilities relative to assets and liabilities outstanding. Right: acquisition of assets and incurrence of liabilities to GDP. The panels are highly unbalanced. Figure A.4 shows the time-varying size of the cross-section. To extract the outflow factor, I choose the time period from 2001 Q3 to 2022 Q3. The country groups for this exercise are:

- **Advanced economies**: Australia, Canada, Croatia, Czechia, Denmark, Estonia, Finland, France, Germany, Greece, Hong Kong, Iceland, Israel, Italy, Japan, Korea, Latvia, Lithuania, Netherlands, Norway, Portugal, Singapore, Slovak Rep., Slovenia, Spain, Sweden, Switzerland, United Kingdom

- **Emerging markets**: Argentina, Armenia, Bangladesh, Belarus, Bolivia, Brazil, Bulgaria, Cambodia, Chile, Colombia, Costa Rica, Ecuador, El Salvador, Georgia, Guatemala, Hungary, India, Indonesia, Kazakhstan, Kyrgyz Rep., Mexico, Moldova, Namibia, North Macedonia, Pakistan, Peru, Philippines, Romania, South Africa, Thailand, Türkiye, Ukraine

I designate the United States, Cyprus, and Malta, who are also available, as offshores.

In addition to the measures of outflows $f_{it}$ and $\overline{f}_{it}$ defined in the main text, I define a GDP-adjusted measure $\tilde{f}_{it}$:

$$\tilde{f}_{it} = \sum_{s=t-3}^{s=t} \frac{FA_{i,s}}{GDP_{i,s-1}} - \sum_{s=t-4}^{s=t-7} \frac{FA_{i,s}}{GDP_{i,s-1}}$$  \hspace{1cm} (A.3)
I interpolate GDP from annual data linearly. Table 13 supplements Table 11 with the same correlations computed for $f_t^{AE}$ and $f_t^{EM}$.

The ordering of correlations for this measure is similar to those for $f_{it}$ and $\bar{f}_{it}$.

B.1 Extracting factors

The balanced panel includes $N = 70$ countries and contains $T = 79$ quarters. The model is

$$f = F\Lambda + \varepsilon \quad (A.4)$$

Here $f$ is a $T \times N$ matrix that collects cross-sections as rows, $f_{it} = f_{it}$. The matrix $F$ is $T \times r$, where $r$ is the number of factors. The matrix $\Lambda$ is $r \times N$ and contains factor loadings. Error terms are in the $T \times N$ matrix $\varepsilon$.

I extract the principal component following Doz et al. (2012). The estimate $S$ of the variance-covariance matrix is

$$S = \frac{1}{T}f'f \quad (A.5)$$

This matrix is $N \times N$. I denote by $\mathbb{D}$ the diagonal $r \times r$ matrix collecting $r$ of its largest eigenvalues, and by $\mathbb{W}$ the $N \times r$ matrix collecting the corresponding eigenvectors as columns. The first $r$ estimated components (the first denoted by $\phi_t$) comprise the columns of the $T \times r$ matrix $\hat{F}$

$$\hat{F} = f\mathbb{W}\mathbb{D}^{-1/2} \quad (A.6)$$

Table 11 shows correlations between in-group averages $\{f_t^{AE}, f_t^{EM}, \bar{f}_t^{AE}, \bar{f}_t^{EM}\}$ and time series measuring the global risk-taking capacity. Table 13 adds correlations for $\{f_t^{AE}, f_t^{EM}\}$. I download the quarterly VIX from the FRED website. It is available until Q4 2022. The asset price factor from Miranda-Agrippino et al. (2020) is available until Q4 2018, the intermediary factor from He et al. (2017) until Q4 2022, and the treasury basis from Jiang et al. (2021) until Q2 2017. The
starting date for all these series, except $\phi_t$, is Q1 1990. My particular vintage of $\phi_t$ starts in Q3 2001, giving the sample about 20 years.

This sample does not have to be balanced and uses more countries. The groups are

- **Advanced economies**: Australia, Austria, Belgium, Canada, Croatia, Czechia, Denmark, Estonia, Finland, France, Germany, Greece, Hong Kong, Iceland, Israel, Italy, Japan, Korea, Latvia, Lithuania, Netherlands, New Zealand, Norway, Portugal, Singapore, Slovak Rep., Slovenia, Spain, Sweden, Switzerland, United Kingdom

- **Emerging markets**: Afghanistan, Albania, Angola, Argentina, Armenia, Aruba, Azerbaijan, Bahamas, Bangladesh, Belarus, Belize, Bhutan, Bolivia, Bosnia and Herzegovina, Brazil, Brunei, Bulgaria, Cabo Verde, Cambodia, Cameroon, Chile, China, Colombia, Congo, Costa Rica, Curaçao and Sint Maarten, Djibouti, Dominican Rep., Ecuador, Egypt, El Salvador, Ethiopia, Fiji, Georgia, Guatemala, Guinea, Guyana, Haiti, Honduras, Hungary, India, Indonesia, Iraq, Jamaica, Jordan, Kazakhstan, Kiribati, Kosovo, Kuwait, Kyrgyz Rep., Laos, Lebanon, Lesotho, Madagascar, Malaysia, Mauritania, Mauritius, Mexico, Moldova, Mongolia, Montenegro, Morocco, Mozambique, Myanmar, Namibia, Nepal, Nicaragua, Nigeria, North Macedonia, Pakistan, Papua New Guinea, Paraguay, Peru, Philippines, Poland, Qatar, Romania, Russia, Rwanda, Samoa, Saudi Arabia, Serbia, Sint Maarten, Solomon Islands, South Africa, Sri Lanka, Sudan, Suriname, São Tomé and Príncipe, Tajikistan, Tanzania, Thailand, Tonga, Trinidad and Tobago, Türkiye, Uganda, Ukraine, Uruguay, Uzbekistan, Vanuatu, Venezuela, Vietnam, West Bank and Gaza, Yemen, Zambia, Zimbabwe

- **Offshores**: Bahrain, Bermuda, Cyprus, Ireland, Luxembourg, Malta, Panama, Seychelles, Timor-Leste, United States

Having extracted the factor, I run the following specification in the main text:

$$\bar{f}_{it} = \alpha_i + \gamma \phi_t + \beta_1 \{i \in AE\} \phi_t + \varepsilon_{it} \quad (A.7)$$

An alternative, less flexible specification shuts down country-specific intercepts:

$$\bar{f}_{it} = \alpha + \gamma \phi_t + \beta_1 \{i \in AE\} \phi_t + \varepsilon_{it} \quad (A.8)$$

This removes country fixed effects. Alternatively, I can make the specification more flexible by replacing $\gamma \phi_t$ with quarter-specific intercepts:

$$\bar{f}_{it} = \alpha + \gamma_t + \beta_1 \{i \in AE\} \phi_t + \varepsilon_{it} \quad (A.9)$$

This adds time fixed effects. Table 14 shows that the results are very similar across specifications. The central column corresponds to the baseline from the main text.
Table 14: the dependent variable $f_{it}$ is expressed as percentage.

### B.2 Variance decomposition

The variance of these size-adjusted flows can be decomposed into time-series dispersion of the averages $\bar{f}_t$ or $f_t$, and cross-sectional dispersion around these averages. Taking $\bar{f}_{it}$, 

$$ \nabla[\bar{f}_{it}] = \nabla[\mathbb{E}[\bar{f}_{is}|s = t]] + \mathbb{E}[\nabla[\bar{f}_{is}|s = t]] $$  \hspace{1cm} (A.10)

Table 15: Decomposition of total variance of $\bar{f}_{it}$ within advanced economies and emerging markets. The sample spans Q1 2003 through Q4 2022 and contains 28 AE and 47 EM on average.

<table>
<thead>
<tr>
<th></th>
<th>standard deviation of $\bar{f}_{it}$</th>
<th>total variance</th>
<th>aggregate</th>
<th>idiosyncratic</th>
</tr>
</thead>
<tbody>
<tr>
<td>advanced economies</td>

<td>0.0107</td>
<td><strong>0.0020</strong></td>
<td>0.0087</td>
</tr>
<tr>
<td>emerging markets</td>
<td>0.21</td>
<td>0.0456</td>
<td><strong>0.0012</strong></td>
<td>0.0444</td>
</tr>
</tbody>
</table>

Table 15 shows this decomposition conditional on advanced economies and emerging markets. Importantly, the aggregate component is larger in advanced economies. Not only are the average outflows from advanced economies more tightly connected to aggregates, but they are also more volatile.

Table 16: Decomposition of variance in $f_{it}$ between advanced economies and emerging markets.

<table>
<thead>

<td><strong>0.0001</strong></td>
<td>0.0025</td>
</tr>
</tbody>
</table>

Table 16 is the analog of Table 15 for flows adjusted by GDP. The differences between advanced economies and emerging markets are so much more pronounced because advanced economies have more external assets relative to GDP. Figure A.5 shows the ratio between average assets over GDP in advanced economies and emerging markets, $\frac{f_{AE}}{f_{EM}}$. It also shows the same ratio for liabilities over GDP. Advanced economies accumulate more assets relative to the size of their economies, so
it is not particularly surprising that purchases and sales of foreign assets adjusted for output are larger in magnitude in these countries.

Figure A.5: Ratio of average assets-to-GDP and liabilities-to-GDP in advanced economies and emerging markets.

The synchronization of GDP-adjusted measures of flow with the global flows is also more pronounced in advanced economies. Figure A.6 shows the analog of Figure A.3 for $f_{AE}^t$ and $f_{EM}^t$. Emerging markets look even less synchronized with the global capital flows than on Figure A.3 since $\phi_t$ on these pictures is normalized to have a standard deviation that is the average of that of $f_{AE}^t$ and $f_{EM}^t$, and these two are substantially different. Using position-adjusted flows, as I do in Appendix A, is more informative because they are commensurate in size across advanced and emerging economies and because they capture the intensity of trading relative to wealth, which has a very different relationship to output in different countries.

Figure A.6: Aggregate outflows from advanced economies and emerging markets as a percentage of GDP. Black line: outflow factor $\phi_t$ normalized to have the average standard deviation between $f_{AE}^t$ and $f_{EM}^t$. Error bands show cross-sectional standard deviations of $\overline{f}_{it}$ in the two groups for each quarter $t$.

Figure A.7 presents the time series of cross-sectional size for advanced economies and emerging markets. Advanced economies dominate the sample of position-adjusted outflows before 2008, but
the groups are of comparable size. After 2008, emerging markets overtake advanced economies, outnumbering them by slightly more than two times at the peak. The idiosyncratic component of the total variance in the emerging market panel is five times larger. In the sample of outflows normalized by GDP, they always outnumber advanced economies by 2-2.5 times, and the idiosyncratic component of the total variance is 9 times smaller.

Figure A.7: Number of countries in the sample for the two groups: advanced economies and emerging markets. Left: the panel of outflows normalized by positions. Right: the panel of outflows normalized by GDP.
C Details of portfolio choice

In this section, I derive the portfolio choice of the agents and characterize their value functions. This setup features wealth migration between countries. Appendix D shows a specification with discount rates that vary with wealth instead.

**Regular country savers.** I start with the savers from regular countries. The evolution of an individual saver’s $w_{it}$ given her country’s aggregate wealth $\bar{w}_{it}$ is

$$dw_{it} = (r_tw_{it} - c_{it})dt + \theta_{it}w_{it}dR_{it} + \frac{w_{it}}{\bar{w}_{it}} \cdot \hat{\lambda}\hat{w}_{t}dt - \frac{w_{it}}{\bar{w}_{it}} \cdot \lambda w_{it}dt$$  \hspace{1cm} (A.11)

Here $c_{it}$ is consumption, and the first term in equation (A.11) represents the consumption-savings trade-off. The second term represents returns on the domestic tree, where $\theta_{it}$ is its portfolio share that the saver chooses. She still operates under a portfolio constraint $\theta_{it} \leq \theta$.

The last two terms represent exogenous migration in and out of regular countries. The third term in equation (A.11) represents wealth immigration from the special country. Savers in that country die with intensity $\hat{\lambda}$, and their money is sent to one of the regular countries, where it is shared between the local savers in proportion to net worth. The destination country is chosen uniformly, so each country $i$ has an influx of wealth $\hat{\lambda}\hat{w}_{t}dt$, where $\hat{w}_{t}$ is the special country’s wealth. In $i$, each saver gets a share $w_{it}/\bar{w}_{it}$ of this transfer.

Finally, the fourth term represents emigration to the special country. In regular countries, savers die with an intensity $\lambda$, and their wealth is sent to the special country. The total outflow of money from $i$ is $\lambda w_{it}dt$. New savers are born instead. They start with zero wealth and instantly get transferred a portion of everyone’s savings so that everyone within the country has the same net worth. This redistribution from continuing savers is in proportion to their $w_{it}$. Hence, conditional on continuing, they always make flow payments $\lambda w_{it}dt$ to the newborns.

The sequence problem of the saver in the country $i$ is

$$V_{it} = \max_{(c_{is},\theta_{is})_{s \geq t}} \mathbb{E}_{t} \left[ \rho \int_{t}^{\infty} e^{\rho(t-s)} \log(c_{is})ds \right]$$  \hspace{1cm} (A.12)

subject to equation (A.11) and $\theta_{it} \leq \theta$. Savers choose consumption rate and the portfolio share allocated to risky assets. They take the interest rate $r_t$, tree price $p_{it}$, and aggregate net worth $\bar{w}_{it}$ as given. The discount rate $\rho$ is constant.

Since everyone has the same $w_{it}$, in equilibrium $w_{it} = \bar{w}_{it}$, and the evolution of the total wealth in country $i$ is

$$dw_{it} = (r_tw_{it} - c_{it})dt + \theta_{it}w_{it}dR_{it} + (\hat{\lambda}\hat{w}_{t} - \lambda w_{it})dt$$

The proposition below characterizes the solution to their problem in equation (A.12).
Proposition 2. Given the time paths of the global interest rate \( r_t \), the special country’s wealth \( \hat{w}_t \), and the drift and volatility of the excess return process \( (\mu^R_{it}, \sigma^R_{it}) \),

\[
V_{it} = \log(\rho w_{it}) + \kappa(w_{it}, t)
\]

(A.13)

where \( \kappa(w_{it}, t) \) satisfies a partial differential equation. Consumption and portfolio choice are

\[
c_{it} = \rho w_{it}
\]

(A.14)

\[
\theta_{it} = \min \left\{ \theta, \frac{\mu^R_{it}}{\sigma^R_{it}} \right\}
\]

(A.15)

Proof of Proposition 2. Since there is no aggregate uncertainty, state variables for a saver in country \( i \) are her own wealth \( w_{it} \), aggregate wealth of her country \( w_{it} \), and time \( t \). Dropping the subscript \( i \), define the drift and volatility of \( w_{it} \) and \( w_{it} \):

\[
dw = \mu_w(w, t) dt + \sigma_w(w, t) dZ
\]

(A.16)

\[
dw = \mu_w(w, w, t; c, \theta) dt + \sigma_w(w, w, t; \theta) dZ
\]

(A.17)

The saver correctly assesses the functions \( \mu_w(w, t) \) and \( \sigma_w(w, t) \) but does not internalize the effect of her choices on \( w \). The drift and volatility of individual wealth depend on consumption and portfolio choice \( (c, \theta) \):

\[
\mu_w(w, w, t; c, \theta) = r(t)w - c + \theta \mu_R(w, t)w + w \left( \lambda \frac{\hat{w}(t)}{w} - \lambda \right)
\]

(A.18)

\[
\sigma_w(w, w, t; \theta) = \theta \sigma_R(w, t)w
\]

(A.19)

Here the dependence on time comes from the drift and volatility of returns \( \mu_R(w, t) \) and \( \sigma_R(w, t) \) as well as the global interest rate \( r(t) \) and the net worth of the special country \( \hat{w}(t) \). The HJB equation for the saver’s value \( V(w, w, t) \) is, suppressing the arguments,

\[
\rho V - \partial_t V = \max_{c, \theta \leq \theta} \rho \log(c) + \mu_w(w, w, t; c, \theta) \partial_w V + \frac{\sigma_w(w, w, t; \theta)^2}{2} \partial_{ww} V
\]

\[
+ \mu_w(w, t) \partial_w V + \frac{\sigma_w(w, t)^2}{2} \partial_{ww} V + \sigma_w(w, t) \sigma_w(w, w, t; \theta) \partial_{ww} V
\]

(A.20)

Now guess that the value function \( V(w, w, t) \) has the following form:

\[
V(w, w, t) = \log(\rho w) + \kappa(w, t)
\]

(A.21)
Plugging this into equation (A.20),

\[ \rho \log(\rho w) + \rho \kappa(w, t) - \partial_t \kappa(w, t) = \max_{c, \theta \leq \overline{\theta}} \rho \log(c) + \frac{\mu_w(w, w; c, \theta)}{w} - \frac{\sigma_w(w, w; t, \theta)^2}{2w^2} \]

\[ + \frac{\mu_w(w, t)\partial_w \kappa(w, t)}{2} + \frac{\mu_{w}(w, t)^2}{2} \partial_{ww} \kappa(w, t) \]  

(A.22)

Notice that the cross-derivative term drops out. Now using the functional forms for \( \mu_w(w, w; c, \theta) \) and \( \sigma_w(w, w; t, \theta) \) from equation (A.18) and equation (A.19), the optimal choices are

\[ c^* = \rho w \]  

(A.23)

\[ \theta^* = \min \left\{ \frac{\mu_R(w, t)}{\sigma_R(w, t)^2}, \overline{\theta} \right\} \]  

(A.24)

This shows that savers consume a constant fraction of their wealth and choose a mean-variance portfolio whenever they can.

To get the partial differential equation that describes \( \kappa(w, t) \), use the consistency requirement \( w = w \), which also implies \( \mu_w(w, t) = \mu_w(w, w; c^*, \theta^*) \) and \( \sigma_w(w, t) = \sigma_w(w, w; t; \theta^*) \). Plugging this into equation (A.23) and equation (A.22),

\[ \rho \kappa(w, t) - \partial_t \kappa(w, t) = \frac{\mu_w(w, t)}{w} - \frac{\sigma_w(w, t)^2}{2w^2} + \frac{\mu_w(w, t)}{2} \partial_w \kappa(w, t) + \frac{\sigma_w(w, t)^2}{2} \partial_{ww} \kappa(w, t) \]  

(A.25)

Boundary conditions for this equation in general depend on the properties of loadings \( \mu_R(w, t) \) and \( \sigma_R(w, t) \). Plugging the optimal choice of controls in equation (A.23) and equation (A.24),

\[ \mu_w(w, t) = (r(t) - \rho - \lambda)w + \hat{\lambda} \hat{\omega}(t) + \min \left\{ \frac{\mu_R(w, t)}{\sigma_R(w, t)^2}, \overline{\theta} \right\} \mu_R(w, t)w \]  

(A.26)

\[ \sigma_w(w, t) = \min \left\{ \frac{\mu_R(w, t)}{\sigma_R(w, t)^2}, \overline{\theta} \right\} \sigma_R(w, t)w \]  

(A.27)

At \( w = 0 \), the drift of wealth is not equal to zero. This property helps avoid \( w = 0 \) being an absorbing state. However, \( \kappa(w, t) \) might diverge around small \( w \). Assuming that \( \mu_R(w, t) \) is bounded, the limiting behavior of \( \kappa(w, t) \) around \( w = 0 \) is

\[ \lim_{x \to 0} \frac{\kappa(x, t)}{\log(x)} = -1 \]  

(A.28)

Assuming that \( \mu_R(w, t)/\sigma_R(w, t) \) approaches zero as \( w \to \infty \),

\[ \lim_{x \to \infty} \rho \kappa(x, t) - \partial_t \kappa(x, t) = r(t) - \rho - \lambda \]  

(A.29)

The last remaining piece is a suitable initial or terminal condition. In practice, I will use the
The problem of an individual intermediary is an inflow of problem for a finite number of countries and then let the number of countries grow to infinity. I next describe the special country. The individual net worth \( \hat{w}_t \) of an intermediary, who is also a saver in the special country, evolves as

\[
d\hat{w}_t = (r_t \hat{w}_t - \hat{c}_t)dt + \sum_i \hat{\theta}_{it} \hat{w}_t dR_{it} + \hat{\theta}_t \hat{w}_t d\hat{R}_t + \frac{\hat{w}_t}{\hat{w}_t} \cdot \lambda w_t dt - \frac{\hat{w}_t}{\hat{w}_t} \cdot \hat{\lambda} \hat{w}_t dt \quad (A.30)
\]

Consumption is \( \hat{c}_t \) and \( \hat{w}_t \) is the special country’s aggregate wealth. The second and third terms are excess returns on trees in regular countries and at home. Positions \((\hat{\theta}_{it}, \hat{\theta}_t)\) are akin to \( \theta_{it} \) in the regular country’s problem. Portfolios with a continuum of idiosyncratic returns require special care, so I write the total return as a sum without specifying its type. Below, I work out this problem for a finite number of countries and then let the number of countries grow to infinity.

The last two terms are the mirror image of wealth migration terms in equation (1): there is an inflow of \( \lambda w_t dt \), where \( w_t = \int_0^1 w_{it} di \) is the aggregate wealth of the regular countries, and an outflow of \( \hat{\lambda} \hat{w}_t dt \). Again, as in regular countries, newborn savers immediately receive transfers from everyone else so that everyone’s wealth is the same.

The individual wealth \( \hat{w}_t \) of the special country savers aggregates into \( \hat{w}_t \) evolving as

\[
d\hat{w}_t = (r_t \hat{w}_t - \hat{c}_t)dt + \sum_i \hat{\theta}_{it} \hat{w}_t dR_{it} + \hat{\theta}_t \hat{w}_t d\hat{R}_t + (\lambda w_t - \hat{\lambda} \hat{w}_t)dt \quad (A.31)
\]

Taking into account drift corrections, the evolution of an individual intermediary’s net worth can be rewritten as

\[
d\hat{w} = (r_t \hat{w}_t - \hat{c}_t)dt + \sum_i \hat{\theta}_{it} \hat{w}_t ((\mu_{it}^R - \sigma_{it}^R \xi_{it})dt + \sigma_{it}^R d\tilde{Z}_{it}) + \hat{\theta}_t \hat{w}_t d\hat{R}_t + \frac{\hat{w}_t}{\hat{w}_t} (\lambda w_t - \hat{\lambda} \hat{w}_t)dt \quad (A.32)
\]

The problem of an individual intermediary is

\[
\hat{V}_t = \max_{\{\hat{c}_t, \hat{\theta}_t, \hat{f}_t\}_{t \geq t}} \inf_{Q \in \mathcal{Q}} \mathbb{E}_t^Q \left[ \hat{\rho} \int_t^\infty e^{\hat{\rho}(s-t)} \log(\hat{c}_s)ds + \frac{1}{2} \int_t^\infty e^{\hat{\rho}(s-t)} \hat{\gamma}_s \sum_i \eta(w_{is})dm_{is} \right] \quad (A.33)
\]

subject to equation (A.32). Note a constant discount rate \( \hat{\rho} \).

**Proposition 3.** Fix the number of regular countries at \( n \). Given the path of the global interest rate \( r_t \) and the vector \( x_t \) of aggregate wealth in every country including \( \hat{w}_t \), the value function of an individual special country saver is

\[
\hat{V}_t^{(n)} = \log(\hat{\rho} \hat{w}_t) + \hat{k}^{(n)}(x_t, t) \quad (A.34)
\]
The function \( \hat{k}_t \) solves a first-order ordinary differential equation. The choice of portfolio weights and drift correction for each country \( i \) is

\[
\begin{align*}
    f_{it}^{(n)} &= \frac{\hat{\gamma}_t \eta(w_{it})}{1 + \hat{\gamma}_t \eta(w_{it})} \cdot \frac{\mu^R_{it}}{(\sigma^R_{it})^2} \\
    \xi_{it}^{(n)} &= \frac{1}{\hat{\gamma}_t \eta(w_{it})} \cdot f_{it}^{(n)} \sigma^R_{it} = \frac{1}{1 + \hat{\gamma}_t \eta(w_{it})} \cdot \frac{\mu^R_{it}}{\sigma^R_{it}}
\end{align*}
\]  

(A.35)  

(A.36)

**Proof of Proposition 3.** Fix the number of regular countries \( n \). The state variables of the global bank are its wealth \( \hat{w} \), a vector \( x \) that combines aggregate special country wealth \( \hat{w} \) and all other \( (w_i) \), and time \( t \) that summarizes all other variables. The evolution of individual wealth \( \hat{w} \) is

\[
d\hat{w} = (r_t \hat{w}_t - \hat{c}_t)dt + \sum_i \hat{\theta}_i \hat{w}_i ((\mu^R_{it} - \sigma^R_{it} \xi_{it}) dt + \sigma^R_{it} d\hat{Z}_{it}) + \hat{\theta}_i \hat{w}_i d\hat{R}_t
\]  

(A.37)

\[
+ \frac{\hat{w}_t}{\hat{w}_i} (\lambda w_t dt - \hat{\lambda} \hat{w}_t) dt
\]

Combine all \( (d\hat{Z}_{it}) \) into a vector \( d\hat{Z}_t \). Aggregate vector \( x \) evolves as

\[
dx = \mu_x(x, t) dt + \sigma_x(x, t) d\hat{Z}_t
\]  

(A.38)

The HJB equation for \( \hat{V}(\hat{w}, x, t) \) is, suppressing arguments,

\[

\frac{\partial \hat{V}}{\partial t} - \rho \hat{V} = \max \min \hat{c}, \hat{\theta}, (\hat{\theta}_i) (\xi_i) \rho \log(\hat{c}) + \frac{\hat{\gamma}(t)}{2} \sum_i \eta(w_{it}) \xi_{it}^2 + \mu_{\hat{w}}(\hat{w}, x, t; \hat{\theta}, (\hat{\theta}_i, \xi_i)) \partial_{\hat{w}} \hat{V} + \mu_x(x, t)' \partial_x \hat{V}
\]

\[
+ \frac{\sigma_{\hat{w}}(\hat{w}, x, t; (\hat{\theta}_i))^2}{2} \partial_{\hat{w}\hat{w}} V + \frac{1}{2} \text{tr} (\sigma_x(x, t)' \partial_{xx} V \sigma_x(x, t)) + \sigma_{\hat{w}x}(\hat{w}, x, t; (\hat{\theta}_i))' \partial_{\hat{w}x} V
\]

(A.39)

Here the drift and variance of \( \hat{w} \) conditional on controls \( c, \hat{\theta}, (\hat{\theta}_i) \), and \( (\xi_i) \) are

\[

\begin{align*}
    \mu_{\hat{w}}(\hat{w}, x, t; \hat{\theta}, (\hat{\theta}_i, \xi_i)) &= (r_t - \hat{\lambda} + E_t[\hat{R}_t]) \hat{w} - c + \sum_i \hat{\theta}_i (\mu_{it}^R - \xi_{it}^R) + \frac{w(t)}{\hat{w}(t)} \lambda \hat{w}
\end{align*}
\]  

(A.40)

\[

\begin{align*}
    \sigma_{\hat{w}}(\hat{w}, x, t; (\hat{\theta}_i))^2 &= \hat{w}^2 \sum_i \hat{\theta}_i^2 (\sigma_{it}^R)^2
\end{align*}
\]  

(A.41)

\[

\sigma_{\hat{w}x}(\hat{w}, x, t; (\hat{\theta}_i)) = \hat{w} \sigma_x(x, t) v(x, t, (\hat{\theta}_i))
\]

(A.42)

The vector \( v(x, t, (\hat{\theta}_i)) \) in equation (A.42) collects the products \( (\hat{\theta}_i \sigma_{it}^R) \).

The solution for the weight on the special country’s tree \( \hat{\theta} \) will only be finite if \( E_t[d\hat{R}_t] = 0 \). I assume that this is the case. The optimal weight \( \hat{\theta}^* \) is not determined and does not affect the value of the objective, so I will omit it from the notation for \( \mu_{\hat{w}}(\hat{w}, x, t; \hat{\theta}, (\hat{\theta}_i, \xi_i)) \) below.
The expressions for variance of $d\hat{w}$ and co-variance of $d\hat{w}$ and $dx$ per unit of time in equation (A.41) and equation (A.42) use independence between $d\tilde{Z}_{it}$.

Solving the minimization problem over $(\xi_i)$,

$$\xi_i^* = \frac{1}{\gamma(t)\eta(w_{it})} \cdot \hat{\theta}_i \sigma^R_{it} \cdot \hat{w}\partial \hat{V}$$ \hspace{1cm} (A.43)

Plugging this into equation (A.40),

$$\mu_{\hat{w}}(\hat{w}, x, t; \hat{c}, (\hat{\theta}_i, \xi_i^*)) = (r(t) - \hat{\lambda})\hat{w} - \hat{c} + \sum_i \left( \hat{w}\hat{\theta}_i \sigma^R_{it} - \frac{(\hat{w}\sigma^R_{it})^2}{\gamma(t)\eta(w_{it})} \hat{\theta}_i^2 \right) + \frac{w(t)}{\hat{w}(t)}\lambda\hat{w}$$ \hspace{1cm} (A.44)

The problem in equation (A.39) is now

$$\hat{\rho}\hat{V} - \partial_t \hat{V} = \max_{\hat{c}, (\hat{\theta}_i)} \hat{\rho} \log(\hat{c}) + \left( \frac{(\hat{w}\sigma^R_{it})^2}{2\gamma(t)} \right) \sum_i \frac{w(t)}{\hat{w}(t)} \hat{\theta}_i^2 + \mu_{\hat{w}}(\hat{w}, x, t; \hat{c}, (\hat{\theta}_i, \xi_i^*)) \partial_{\hat{w}} \hat{V} + \mu_x(x, t)' \partial x \hat{V}$$

$$+ \frac{\sigma_{\hat{w}}(\hat{w}, x, t; (\hat{\theta}_i))^2}{2} \partial_{\hat{w}^2} \hat{V} + \frac{1}{2} \text{tr}(\sigma_x(x, t) \partial x' V \sigma_x(x, t)) + \sigma_{\hat{w}x}(\hat{w}, x, t; (\hat{\theta}_i))' \partial_{\hat{w}x} \hat{V}$$ \hspace{1cm} (A.45)

Plugging equation (A.44) and equation (A.41) into this,

$$\hat{\rho}\hat{V} - \partial_t \hat{V} = \max_{\hat{c}, (\hat{\theta}_i)} \hat{\rho} \log(\hat{c}) - \hat{c} \partial_{\hat{w}} \hat{V} + \partial_{\hat{w}} \hat{V} \sum_i \hat{w}\mu^R_{it} \hat{\theta}_i - \frac{(\hat{w}\sigma^R_{it})^2}{2\gamma(t)} \sum_i \frac{w(t)}{\hat{w}(t)} \hat{\theta}_i^2$$

$$+ \left( r(t) - \hat{\lambda} + \lambda \frac{w(t)}{\hat{w}(t)} \right) \hat{w}\partial_{\hat{w}} \hat{V} + \hat{w}^2 \sum_i \frac{\hat{\theta}_i^2 (\sigma^R_{it})^2}{2} \partial_{\hat{w}^2} \hat{V}$$

$$+ \mu_x(x, t)' \partial x \hat{V} + \frac{1}{2} \text{tr}(\sigma_x(x, t) \partial x' V \sigma_x(x, t)) + \sigma_{\hat{w}x}(\hat{w}, x, t; (\hat{\theta}_i))' \partial_{\hat{w}x} \hat{V}$$ \hspace{1cm} (A.46)

Guess that the value function $\hat{V}(\hat{w}, t)$ has the following form

$$\hat{V}(\hat{w}, x, t) = \log(\hat{\rho}\hat{w}) + \hat{\kappa}(x, t)$$ \hspace{1cm} (A.47)

This immediately leads to the optimal choice of consumption:

$$\hat{c}_t^* = \hat{\rho}\hat{w}$$ \hspace{1cm} (A.48)

Replacing this in equation (A.46),

$$\hat{\rho}\hat{\kappa}(x, t) - \partial_t \hat{\kappa}(x, t) = \max_{(\hat{\theta}_i)} \sum_i \left( \mu^R_{it} \hat{\theta}_i - \frac{(\sigma^R_{it})^2}{2\gamma(t)\eta(w_{it})} \hat{\theta}_i^2 - \frac{(\sigma^R_{it})^2}{2} \hat{\theta}_i^2 \right) + r(t) - \hat{\rho} - \hat{\lambda} + \frac{\lambda w(t)}{\hat{w}(t)}$$

$$+ \mu_x(x, t)' \partial x \hat{\kappa}(x, t) + \frac{1}{2} \text{tr}(\sigma_x(x, t) \partial x' \hat{\kappa}(x, t) \sigma_x(x, t))$$ \hspace{1cm} (A.49)
The optimal choice of portfolio weights ($\hat{\theta}_i$) is

$$\hat{\theta}_i^* = \frac{\hat{\gamma}(t)\eta(w_{it})}{1 + \hat{\gamma}(t)\eta(w_{it})} \cdot \frac{\mu_{it}^R}{(\sigma_{it}^R)^2} \tag{A.50}$$

This leads to the following expression for the optimal drift correction:

$$\xi_i^* = \frac{1}{1 + \hat{\gamma}(t)\eta(w_{it})} \cdot \frac{\mu_{it}^R}{\sigma_{it}^R} \tag{A.51}$$

The differential equation for $\hat{\kappa}(t)$ becomes

$$\hat{\rho}\hat{\kappa}(x, t) - \partial_t \hat{\kappa}(\hat{w}, t) = \frac{1}{2} \sum_i \frac{\hat{\gamma}(t)\eta(w_{it})}{1 + \hat{\gamma}(t)\eta(w_{it})} \left( \frac{\mu_{it}^R}{\sigma_{it}^R} \right)^2 + r(t) - \hat{\rho} - \hat{\lambda} + \frac{\lambda w(t)}{\hat{w}(t)}$$

$$+ \mu_x(x, t)^t \partial_x \hat{\kappa}(x, t) + \frac{1}{2} \text{tr}(\sigma_x(x, t)^t \partial_{xx} \hat{\kappa}(x, t)\sigma_x(x, t)) \tag{A.52}$$

The last remaining piece is a suitable initial or terminal condition. In practice, I will use the steady-state value of $\hat{\kappa}$ as the terminal limit at $t \to \infty$. □
D Portfolio choice with time-varying discounting

In this section, I derive the portfolio choice of the agents and characterize their value functions under a specification without wealth migration and with subjective discount rates that vary with wealth. The main takeaway from this exercise is that portfolio choice and aggregate consumption are the same as in the baseline.

Regular country savers. I start with the savers from regular countries. The proposition below characterizes the solution to their problem in equation (A.12).

**Proposition 4.** Given the time paths of the global interest rate $r_t$, the special country’s wealth $\hat{w}_t$, and the drift and volatility of the excess return process $(\mu^R_{it}, \sigma^R_{it})$,

$$V_{it} = \log(\varrho_{it}w_{it}) + \kappa(w_{it}, t)$$  \hspace{1cm} \text{(A.53)}

where $\kappa(w_{it}, t)$ satisfies a partial differential equation. Consumption and portfolio choice are

$$c_{it} = \varrho_{it}w_{it}$$  \hspace{1cm} \text{(A.54)}

$$\theta_{it} = \min\left\{\hat{\theta}, \frac{\mu^R_{it}}{(\sigma^R_{it})^2}\right\}$$  \hspace{1cm} \text{(A.55)}

**Proof of Proposition 4.** Since there is no aggregate uncertainty, state variables for a saver in country $i$ are her own wealth $w_{it}$, aggregate wealth of her country $\hat{w}_{it}$, and time $t$. Dropping the subscript $i$, define the drift and volatility of $w_{it}$ and $\hat{w}_{it}$:

$$dw = \mu_w(w, w, t; c, \theta)dt + \sigma_w(w, w, t; \theta)dZ$$  \hspace{1cm} \text{(A.56)}

$$d\hat{w} = \mu_{\hat{w}}(w, t)dt + \sigma_{\hat{w}}(w, t)dZ$$  \hspace{1cm} \text{(A.57)}

The saver correctly assesses the functions $\mu_w(w, t)$ and $\sigma_w(w, t)$ but does not internalize the effect of her choices on $w$. The drift and volatility of individual wealth depend on consumption and portfolio choice $(c, \theta)$:

$$\mu_w(w, w, t; c, \theta) = r(t)w - c + \theta\mu_R(w, t)w$$  \hspace{1cm} \text{(A.58)}

$$\sigma_w(w, w, t; \theta) = \theta\sigma_R(w, t)w$$  \hspace{1cm} \text{(A.59)}

Here the dependence on time comes from the global interest rate $r(t)$, the net worth of the special country $\hat{w}(t)$, and time-dependent terms $\mu^R(w, t)$ and $\sigma^R(w, t)$. The HJB equation for the saver’s
value $V(w, w, t)$ is, suppressing the arguments,

$$\rho V - \partial_t V = \max_{c, \theta \leq \theta^*} \rho \log(c) + \mu_w(w, w, t; c, \theta) \partial_w V + \frac{\sigma_w(w, w, t; \theta)^2}{2} \partial_{ww} V$$

$$+ \mu_w(w, t) \partial_w V + \frac{\sigma_w(w, t)^2}{2} \partial_{ww} V + \sigma_w(w, t) \sigma_w(w, w, t; \theta) \partial_{ww} V$$  \hspace{1cm} (A.60)

Now guess that the value function $V(w, w, t)$ has the following form:

$$V(w, w, t) = \log(w) + \log(\varphi(w, t)) + \kappa(w, t)$$  \hspace{1cm} (A.61)

Plugging this into equation (A.60) and suppressing arguments of $\varphi(w, t)$ again,

$$\rho \log(w) + \rho \kappa(w, t) - \partial_t \kappa(w, t) = \max_{c, \theta \leq \theta^*} \rho \log(c) + \frac{\mu_w(w, w, t; c, \theta)}{w} - \frac{\sigma_w(w, w, t; \theta)^2}{2w^2}$$

$$+ \mu_w(w, t) \partial_w \kappa(w, t) + \frac{\sigma_w(w, t)^2}{2} \partial_{ww} \kappa(w, t)$$  \hspace{1cm} (A.62)

Notice that the cross-derivative term drops out. Now using the functional forms for $\mu_w(w, w, t; c, \theta)$ and $\sigma_w(w, w, t; \theta)$ from equation (A.58) and equation (A.59), the optimal choices are

$$c^* = \varphi(w, t) w$$  \hspace{1cm} (A.63)

$$\theta^* = \min \left\{ \frac{\mu_R(w, t)}{\sigma_R(w, t)^2}, \theta \right\}$$  \hspace{1cm} (A.64)

This shows that savers consume a constant fraction of their wealth and choose a mean-variance portfolio whenever they can.

To get the partial differential equation that describes $\kappa(w, t)$, use the consistency requirement $w = w$, which also implies $\mu_w(w, t) = \mu_w(w, w, t; c^*, \theta^*)$ and $\sigma_w(w, t) = \sigma_w(w, w, t; \theta^*)$. Plugging this into equation (A.63) and equation (A.62),

$$\rho \kappa(w, t) - \partial_t \kappa(w, t) = \frac{\mu_w(w, t)}{w} - \frac{\sigma_w(w, t)^2}{2w^2} + \mu_w(w, t) \partial_w \kappa(w, t) + \frac{\sigma_w(w, t)^2}{2} \partial_{ww} \kappa(w, t)$$  \hspace{1cm} (A.65)

Boundary conditions for this equation in general depend on the properties of loadings $\mu_R(w, t)$ and $\sigma_R(w, t)$. Plugging the optimal choice of controls and the functional form of $\varphi(w, t)$ in equation (A.63) and equation (A.64),

$$\mu_w(w, t) = (r(t) - \rho - \lambda) w + \hat{\lambda} \hat{w}(t) + \min \left\{ \frac{\mu_R(w, t)}{\sigma_R(w, t)^2}, \theta \right\} \mu_R(w, t) w$$  \hspace{1cm} (A.66)

$$\sigma_w(w, t) = \min \left\{ \frac{\mu_R(w, t)}{\sigma_R(w, t)^2}, \theta \right\} \sigma_R(w, t) w$$  \hspace{1cm} (A.67)
At \( w = 0 \), the drift of wealth is not equal to zero. This property helps avoid \( w = 0 \) being an absorbing state. However, \( \kappa(w, t) \) might diverge around small \( w \). Assuming that \( \mu_R(w, t) \) is bounded, the limiting behavior of \( \kappa(w, t) \) around \( w = 0 \) is

\[
\lim_{x \to 0} \frac{\kappa(x, t)}{\log(x)} = -1 \tag{A.68}
\]

Assuming that \( \mu_R(w, t)/\sigma_R(w, t) \) approaches zero as \( w \to \infty \),

\[
\lim_{x \to \infty} \varrho(x, t)\kappa(x, t) - \partial_t \kappa(x, t) = r(t) - \rho - \lambda \tag{A.69}
\]

The last remaining piece is a suitable initial or terminal condition. In practice, I will use the steady-state value of \( \kappa(w, t) \) as the limiting terminal condition at infinity. Assuming that \( \mu_R(w, t) \) is bounded and \( \mu_R(w, t)/\sigma_R(w, t) \to 0 \) as \( w \to \infty \), this completes the characterization of \( \kappa(w, t) \) given the general equilibrium objects \( r(t), \hat{w}(t), \mu_R(w, t), \) and \( \sigma_R(w, t) \). □

**Problem of the intermediary.** The next proposition deals with the problem of the intermediary, which is also the special country’s saver.

**Proposition 5.** Fix the number of regular countries at \( n \). Given the path of the global interest rate \( r_t \) and the vector \( x_t \) of aggregate wealth in every country including \( \hat{w}_t \), the value function of an individual special country saver is

\[
\hat{V}_t^{(n)} = \log(\hat{\varrho}_t\hat{w}_t) + \hat{\kappa}^{(n)}(x_t, t) \tag{A.70}
\]

The function \( \hat{\kappa}^{(n)}_i \) solves a first-order ordinary differential equation. The choice of portfolio weights and drift correction for each country \( i \) is

\[
\hat{\theta}_i^{(n)} = \frac{\hat{\gamma}_i \eta(w_i)}{1 + \hat{\gamma}_i \eta(w_i)} \cdot \frac{\mu_{R_i}}{(\sigma_{R_i})^2} \tag{A.71}
\]

\[
\xi_i^{(n)} = \frac{1}{\hat{\gamma}_i \eta(w_i)} \cdot \frac{1}{1 + \hat{\gamma}_i \eta(w_i)} \cdot \frac{\mu_{R_i}}{\sigma_{R_i}} \tag{A.72}
\]

**Proof of Proposition 5.** Fix the number of regular countries \( n \). The state variables of the global bank are its wealth \( \hat{w} \), a vector \( x \) that combines aggregate special country wealth \( \hat{w} \) and all other \( (w_i) \), and time \( t \) that summarizes all other variables. The evolution of individual wealth \( \hat{w} \) is

\[
d\hat{w} = (r_t \hat{w} - \hat{c}_t)dt + \sum_i f_{it} \hat{w}_t ((\mu_{it} - \sigma_{it} \xi_{it})dt + \sigma_{it} d\tilde{Z}_{it}) + \hat{\theta}_i \hat{w}_t d\hat{R}_t \tag{A.73}
\]
Combine all \((d\tilde{Z}_t)\) into a vector \(d\tilde{Z}_t\). Aggregate vector \(x\) evolves as

\[dx = \mu_x(x,t)dt + \sigma_x(x,t)d\tilde{Z}_t\]  \hfill (A.74)

The HJB equation for \(\hat{V}(\hat{w}, x, t)\) is, suppressing arguments,

\[
\hat{\theta}V - \partial_t \hat{V} = \max_{\hat{c}, \hat{\theta}, (\hat{\theta}_i)} \hat{\theta} \log(\hat{c}) + \frac{\hat{\gamma}(t)}{2} \sum_i \eta(w_{it}) \xi_i^2 + \mu_{\hat{w}}(\hat{w}, x, t; \hat{c}, \hat{\theta}, (\hat{\theta}_i)) \partial_{\hat{w}} \hat{V} + \mu_x(x,t)' \partial_x \hat{V} \\
+ \frac{\sigma_{\hat{w}}(\hat{w}, x, t; (\hat{\theta}_i))^2}{2} \partial_{\hat{w}\hat{w}} \hat{V} + \frac{1}{2} \text{tr}(\sigma_x(x,t)' \partial_{xx'} V \sigma_x(x,t)) + \sigma_{\hat{w}x}(\hat{w}, x, t; (\hat{\theta}_i))' \partial_{\hat{w}x} \hat{V} \]  \hfill (A.75)

Here the drift and variance of \(\hat{w}\) conditional on controls \(c, \hat{\theta}, (\hat{\theta}_i)\), and \((\xi_i)\) are

\[
\mu_{\hat{w}}(\hat{w}, x, t; \hat{c}, \hat{\theta}, (\hat{\theta}_i)) = (r(t) + \hat{\theta} \mathbb{E}_t[d\hat{R}_i]) \hat{w} - c + \sum_i \hat{\theta}_i \mu_{\hat{w}}(\xi_i) - \xi_i \sigma_{\hat{w}}(\xi_i) \]  \hfill (A.76)

\[
\sigma_{\hat{w}}(\hat{w}, x, t; (\hat{\theta}_i))^2 = \hat{w}^2 \sum_i \hat{\theta}_i^2 \sigma_{\hat{w}}(\xi_i)^2 \]  \hfill (A.77)

\[
\sigma_{\hat{w}x}(\hat{w}, x, t; (\hat{\theta}_i)) = \hat{w} \sigma_x(x,t) v(x,t; (\hat{\theta}_i)) \]  \hfill (A.78)

The vector \(v(x,t; (\hat{\theta}_i))\) in equation (A.78) collects the products \((\hat{\theta}_i, \sigma_{\hat{w}}(\xi_i))\).

The solution for the weight on the special country’s tree \(\hat{\theta}\) will only be finite if \(\mathbb{E}_t[d\hat{R}_i] = 0\). I assume that this is the case. The optimal weight \(\hat{\theta}^*\) is not determined and does not affect the value of the objective, so I will omit it from the notation for \(\mu_{\hat{w}}(\hat{w}, x, t; \hat{c}, \hat{\theta}, (\hat{\theta}_i, \xi_i))\) below.

The expressions for variance of \(d\hat{w}\) and co-variance of \(d\hat{w}\) and \(d\hat{w}\) per unit of time in equation (A.77) and equation (A.78) use independence between \(d\tilde{Z}_t\).

Solving the minimization problem over \((\xi_i)\),

\[
\xi_i^* = \frac{1}{\hat{\gamma}(t) \eta(w_{it})} \cdot \hat{\theta}_i \sigma_{\hat{w}}(\xi_i) \cdot \hat{w} \partial_{\hat{w}} \hat{V} \]  \hfill (A.79)

Plugging this into equation (A.95),

\[
\mu_{\hat{w}}(\hat{w}, x, t; \hat{c}, (\hat{\theta}_i, \xi_i^*)) = r(t) \hat{w} - \hat{c} + \sum_i \left( \hat{\theta}_i \mu_{\hat{w}}(\xi_i) - \partial_{\hat{w}} \hat{V} \frac{(\hat{w} \sigma_{\hat{w}}(\xi_i)^2)}{\hat{\gamma}(t) \eta(w_{it})} \hat{\theta}_i^2 \right) + \frac{w(t)}{\hat{w}(t)} \lambda \hat{w} \]  \hfill (A.80)

The problem in equation (A.75) is now, suppressing the arguments of \(\varrho(x,t)\),

\[
\hat{\theta}V - \partial_t \hat{V} = \max_{\hat{c}, (\hat{\theta}_i)} \hat{\theta} \log(\hat{c}) + \frac{\hat{\gamma}(t)}{2} \sum_i \eta(w_{it}) \hat{\theta}_i^2 \partial_{\hat{w}} \hat{V} + \mu_{\hat{w}}(\hat{w}, x, t; \hat{c}, (\hat{\theta}_i, \xi_i^*)) \partial_{\hat{w}} \hat{V} + \mu_x(x,t)' \partial_x \hat{V} \\
+ \frac{\sigma_{\hat{w}}(\hat{w}, x, t; (\hat{\theta}_i))^2}{2} \partial_{\hat{w}\hat{w}} \hat{V} + \frac{1}{2} \text{tr}(\sigma_x(x,t)' \partial_{xx'} V \sigma_x(x,t)) + \sigma_{\hat{w}x}(\hat{w}, x, t; (\hat{\theta}_i))' \partial_{\hat{w}x} \hat{V} \]  \hfill (A.81)
Plugging equation (A.80) and equation (A.77) into this,

\[
\hat{\phi} \hat{V} - \partial_t \hat{V} = \max_{\hat{c}, \hat{w}} \hat{\phi} \log(\hat{c}) - \hat{c} \partial_{\hat{c}} \hat{V} + \partial_{\hat{w}} \hat{V} \sum_i \hat{w}_i \mu_R \tilde{\theta}_i - \frac{(\partial_{\hat{w}} \hat{V})^2}{2 \hat{\gamma}(t)} \sum_i \frac{\hat{w}_i \sigma_R^2}{\eta(w_{it})} \tilde{\theta}_i^2 \\
+ r(t) \hat{w} \partial_{\hat{w}} \hat{V} + \hat{w}^2 \sum_i \frac{\hat{w}_i^2 (\sigma_R^2)}{2} \partial_{\hat{w}_i \hat{w}_j} \hat{V} \\
+ \mu_x (x, t)' \partial_x \hat{V} + \frac{1}{2} \text{tr}(\sigma_x (x, t)' \partial_{xx} \hat{V} \sigma_x (x, t)) + \sigma_{\hat{w}x} (\hat{w}, x, t; (\hat{\theta}_i))' \partial_{\hat{w}_x} \hat{V}
\] (A.82)

Guess that the value function \(\hat{V}(\hat{w}, x, t)\) has the following form

\[
\hat{V}(\hat{w}, x, t) = \log(\hat{\rho} \hat{w}) + \hat{\kappa}(x, t)
\] (A.83)

This immediately leads to the optimal choice of consumption:

\[
\hat{c}^* = \hat{\phi}(x, t) \hat{w}
\] (A.84)

Replacing this in equation (A.99) and using the functional form for \(\hat{\phi}(x, t)\),

\[
\hat{\phi} \hat{\kappa}(x, t) - \partial_t \hat{\kappa}(x, t) = \max_{\hat{\theta}_i} \sum_i \left( \mu_R \hat{\theta}_i - \frac{(\sigma_R^2)}{2 \hat{\gamma}(t) \eta(w_{it})} \hat{\theta}_i^2 - \frac{(\sigma_R^2)}{2} \hat{\theta}_i^2 \right) + r(t) - \hat{\rho} - \hat{\lambda} + \frac{\lambda w(t) \hat{w}}{\hat{\rho}(t)}
\]
\[
+ \mu_x (x, t)' \partial_x \hat{\kappa}(x, t) + \frac{1}{2} \text{tr}(\sigma_x (x, t)' \partial_{xx} \hat{\kappa}(x, t) \sigma_x (x, t))
\] (A.85)

The optimal choice of portfolio weights \((\hat{\theta}_i)\) is

\[
\hat{\theta}_i = \frac{\hat{\gamma}(t) \eta(w_{it})}{1 + \hat{\gamma}(t) \eta(w_{it})} \cdot \frac{\mu_R}{\sigma_R^2}
\] (A.86)

This leads to the following expression for the optimal drift correction:

\[
\xi_i = \frac{1}{1 + \hat{\gamma}(t) \eta(w_{it})} \cdot \frac{\mu_R}{\sigma_R^2}
\] (A.87)

The differential equation for \(\hat{\kappa}(t)\) becomes

\[
\hat{\phi}(x, t) \hat{\kappa}(x, t) - \partial_t \hat{\kappa}(\hat{w}, t) = \frac{1}{2} \sum_i \frac{\hat{\gamma}(t) \eta(w_{it}) (\mu_R \hat{\theta}_i \sigma_R^2)}{1 + \hat{\gamma}(t) \eta(w_{it})} \hat{\theta}_i^2 + \frac{r(t)}{1 + \hat{\gamma}(t) \eta(w_{it})} + \frac{\lambda w(t) \hat{w}}{\hat{\rho}(t)}
\]
\[
+ \mu_x (x, t)' \partial_x \hat{\kappa}(x, t) + \frac{1}{2} \text{tr}(\sigma_x (x, t)' \partial_{xx} \hat{\kappa}(x, t) \sigma_x (x, t))
\] (A.88)

I use the steady-state value of \(\hat{\kappa}\) as the terminal limit at \(t \to \infty\). □
E Alternative setup for the global banks

This section provides details of the bank’s problem in the continuous limit and an alternative way to model the intermediary using a VAR-type constraint. To simplify notation, I do it in the setup with wealth-dependent discount rates. Everything is the same in the setup with migration.

E.1 Continuous limit

The problem of the bank in the continuous world is

\[
\hat{V}_t = \max_{\{\hat{c}_s, \hat{\theta}_s, f_s\}_{s \geq t}} \inf_{\{\xi_s\}_{s \geq t}} \mathbb{E}_t^Q \left[ \int_t^\infty e^{\hat{\theta}_s(s-t)} \left( \hat{\theta}_t \log(\hat{c}_s) + \frac{\gamma}{2} \int_0^1 \eta(w_{is}) \xi_{is}^2 \, d\xi \right) \, ds \right]
\]  

subject to the budget constraint

\[
d\hat{w} = (r_t \hat{w}_t - \hat{c}_t) \, dt + \int_0^1 \hat{\theta}_it \hat{w}_t((\mu_{it}^R - \sigma_{it}^R \xi_{it}) \, dt + \sigma_{it}^R \hat{Z}_it) \, di + \hat{\theta}_t \hat{w}_t d\hat{R}_t
\]

The bank has access to a continuum of uncorrelated risky assets, so its payoffs are deterministic. However, the bank has freedom to choose a model for uncertainty over each risky asset in its portfolio. Marginal benefits of considering scenarios with more substantial losses (that is, marginal benefits of increasing \(\xi_{it}\)) increase in portfolio weights \(\hat{\theta}_it\). But as the bank entertains more pessimistic models, marginal benefits of raising \(\hat{\theta}_it\) itself decline. This brings decreasing returns into the choice of portfolio weights, even though uncertainty can effectively be disregarded.

**Proposition 6.** Given the paths of the global interest rate \(r_t\), the special country’s aggregate wealth \(\hat{w}_t\), the drift and volatility of the excess return process \((\mu_{it}^R, \sigma_{it}^R)\) for all \(i\), the value function of an individual special country saver is

\[
\hat{V}_t = \log(\hat{\theta}_t \hat{w}_t) + \hat{\kappa}_t
\]

The function \(\hat{\kappa}_t\) solves a first-order ordinary differential equation. The choice of drift correction and portfolio weights for each country \(i\) is

\[
\hat{\theta}_it = \gamma_t \eta(w_{it}) \cdot \frac{\mu_{it}^R}{(\sigma_{it}^R)^2}
\]

\[
\xi_{it} = \frac{1}{\gamma_t \eta(w_{it})} \cdot \hat{\theta}_it \sigma_{it}^R = \frac{\mu_{it}^R}{\sigma_{it}^R}
\]

Portfolio choice of the bank is similar to that of the local savers in regular countries, being proportional to mean over variance of returns. A common factor \(\gamma_t \hat{w}_t\) applies to all regular countries.
 Movements in $\gamma_t$ map into shifts in foreign demand for risky assets in all countries at once. It can be interpreted as a risk-tolerance parameter. Infinite $\gamma_t$ would make the bank essentially neutral to risk, willing to take an arbitrarily large position in any asset that offers excess returns.

Interpreted literally as a cost parameter, high $\gamma_t$ makes the penalty for considering alternative models with large losses prohibitively high. Equation (A.110) shows that, for a fixed $\hat{\theta}_t$, high $\gamma_t$ makes the bank stick closer to the baseline measure. With a smaller correction, marginal costs of increasing $\hat{\theta}_t$ are lower, and the bank demands more risky assets for a given mean-variance ratio.

Why do correction terms $\xi_{it}$ pick up the volatility of idiosyncratic returns if idiosyncratic shocks wash out in aggregate? This is because alternative models chosen by the bank apply to the fundamental dividend shocks. $\xi_{it}$ translates to a mistake in evaluating the expectation of excess returns $dR_{it} = \mu^R_{it} dt + \sigma^R_{it} dZ_{it}$, which is what really matters for portfolio choice, and this latter mistake scales by $\sigma^R_{it}$.

**Proof of Proposition 6.** Since there is no aggregate uncertainty, the evolution of the aggregate wealth in the special country $\hat{w}_t$ and the distribution of $(w_{it})$ can be summarized by time. The HJB equation for $\hat{V}(\hat{w}, t)$ is, suppressing arguments,

$$
\dot{\hat{V}} - \partial_t \hat{V} = \max_{\hat{w}, (f_i), (\xi_i)} \left( \frac{\gamma(t)}{2} \int_0^1 \eta(w_{it}) \xi_i^2 di + \mu^\hat{w}(\hat{w}, t; \hat{c}, \hat{\theta}, (f_i, \xi_i)) \partial_{\hat{w}} \hat{V} \right)
$$

(A.94)

Here the drift of $\hat{w}$ conditional on controls $c$, $\hat{\theta}$, $(f_i)$, and $(\xi_i)$ is

$$
\mu^\hat{w}(\hat{w}, t; \hat{c}, \hat{\theta}, (f_i, \xi_i)) = (r(t) + \mathbb{E}_t[\hat{\theta}d\hat{R}_t])\hat{w} - c + \int_0^1 \hat{w} f_i (\mu^R_{it} - \xi_i \sigma^R_{it}) di
$$

(A.95)

The solution for the weight on the special country’s tree $\hat{\theta}$ will only be finite if $\mathbb{E}_t[d\hat{R}_t] = 0$. I will assume that this is the case henceforth. The optimal weight $\hat{\theta}^*$ is not determined and does not affect the value of the objective, so I will omit it from the notation for $\mu^\hat{w}(\hat{w}, t; \hat{c}, \hat{\theta}^*, (f_i, \xi^*_i))$ below.

Solving the minimization problem over $(\xi_i)$,

$$
\xi^*_i = \frac{1}{\gamma(t)\eta(w_{it})} \cdot f_i \sigma^R_{it} \cdot \hat{w} \partial_{\hat{w}} \hat{V}
$$

(A.96)

Plugging this into equation (A.95),

$$
\mu^\hat{w}(\hat{w}, t; \hat{c}, (f_i, \xi^*_i)) = r(t)\hat{w} - c + \int_0^1 \left( \hat{w} f_i \mu^R_{it} - \partial_{\hat{w}} \hat{V} \frac{(\hat{w} \sigma^R_{it})^2 f_i}{\gamma(t)\eta(w_{it})} \right) di
$$

(A.97)

The problem in equation (A.94) is now, suppressing arguments,

$$
\dot{\hat{V}} - \partial_t \hat{V} = \max_{\hat{w}, (f_i)} \left( \frac{\gamma(t)}{2} \int_0^1 (\hat{w} \sigma^R_{it})^2 f_i^2 di + \mu^\hat{w}(\hat{w}, t; \hat{c}, (f_i, \xi^*_i)) \partial_{\hat{w}} \hat{V} \right)
$$

(A.98)
Plugging equation (A.97) into this,
\[\hat{\varrho} - \partial_t \hat{V} = \max_{\hat{c}, (f_i)} \hat{\varrho} \log(\hat{c}) + (r(t)\hat{w} - \hat{c})\partial_{\hat{w}} \hat{V}\]
+ \partial_{\hat{w}} \hat{V} \int_0^1 \hat{w} \mu^R_{it} f_i di - \frac{(\partial_{\hat{w}} \hat{V})^2}{2\gamma(t)} \int_0^1 \frac{(\hat{w} \sigma^R_{it})^2}{\eta(w_{it})} f_i^2 di \]  
(A.99)

Guess that the value function \(\hat{V}(\hat{w}, t)\) has the following form
\[\hat{V}(\hat{w}, t) = \log(\hat{\varrho}(t)\hat{w}) + \hat{\kappa}(t)\]  
(A.100)

This immediately leads to the optimal choice of consumption:
\[\hat{c}^* = \hat{\varrho}(t)\hat{w}\]  
(A.101)

Replacing this in equation (A.99) and plugging the functional form for \(\varrho(t)\),
\[\hat{\varrho}(t)\hat{\kappa}(t) - \hat{\kappa}'(t) = \max_{(f_i)} \int_0^1 \left( \mu^R_{it} f_i - \frac{(\sigma^R_{it})^2}{2\gamma(t)\eta(w_{it})} f_i^2 \right) di + r(t) - \hat{\rho} - \hat{\lambda} + \frac{\lambda w(t)}{\hat{w}(t)}\]  
(A.102)

The optimal choice of portfolio weights \((f_i)\) is
\[f^*_i = \gamma(t)\eta(w_{it}) \cdot \frac{\mu^R_{it}}{(\sigma^R_{it})^2}\]  
(A.103)

The differential equation for \(\hat{\kappa}(t)\) becomes
\[\hat{\varrho}(t)\hat{\kappa}(t) - \hat{\kappa}'(t) = \frac{\gamma(t)}{2} \int_0^1 \eta(w_{it}) \left( \frac{\mu^R_{it}}{(\sigma^R_{it})^2} \right)^2 di + r(t) - \hat{\rho} - \hat{\lambda} + \frac{\lambda w(t)}{\hat{w}(t)}\]  
(A.104)

The last remaining piece is a suitable initial or terminal condition. In practice, I will use the steady-state value of \(\hat{\kappa}\) as the terminal limit at \(t \to \infty\). \(\square\)

### E.2 VAR-type constraint

The bank with a VAR-type constraint solves
\[\max_{(\hat{c}_s, \hat{\sigma}_s, f_s)_{s \geq t}} \mathbb{E}_t \left[ q_t \int_t^\infty e^{\hat{\varrho}(s-t)} \log(\hat{c}_s) ds \right]\]  
(A.105)
subject to a budget constraint

\[ d\hat{w}_t = (r_t \hat{w}_t - \hat{c}_t)dt + \int_0^1 \hat{\theta}_it \hat{w}_t dR_{it}dt + \hat{\theta}_i \hat{w}_t d\hat{R}_t \]  \hspace{1cm} (A.106)

and the following institutional or regulatory constraint:

\[ \int_0^1 \mathbb{V}_t[\hat{\theta}_idR_{it}]\eta(w_{it})^{-1}di \leq \gamma_t \int_0^1 \mathbb{E}_t[\hat{\theta}_idR_{it}]di \]  \hspace{1cm} (A.107)

The next proposition characterizes the solution.

**Proposition 7.** Given the path of the global interest rate \( r_t \), the special country’s aggregate wealth \( \hat{w}_t \), the drift and volatility of the excess return processes \( (\mu_{it}^R, \sigma_{it}^R) \) for all \( i \), the value function of an individual special country saver with a VAR-type constraint is

\[ \hat{V}_t = \log(\hat{\rho}_t \hat{w}_t) + \hat{\kappa}_t \]  \hspace{1cm} (A.108)

The function \( \hat{\kappa}_t \) solves a first-order ordinary differential equation. The choice of drift correction and portfolio weights for each country \( i \) is

\[ \hat{\theta}_it = \gamma_t \eta(w_{it}) \cdot \frac{\mu_{it}^R}{(\sigma_{it}^R)^2} \]  \hspace{1cm} (A.109)

\[ \xi_{it} = \frac{1}{\gamma_t \eta(w_{it})} \cdot \hat{\theta}_it \sigma_{it}^R = \frac{\mu_{it}^R}{\sigma_{it}^R} \]  \hspace{1cm} (A.110)

**Proof of Proposition 7.** Without aggregate uncertainty, the evolution of the aggregate special country wealth \( \hat{w}_t \) and the cross-section of \( (w_{it}) \) can be summarized by time. The HJB equation for \( \hat{V}(\hat{w}, t) \) is, suppressing arguments,

\[ \hat{\partial}V - \hat{\partial}_t \hat{V} = \max_{\hat{\epsilon}, \hat{\theta}, (\hat{\theta}_i)} \hat{\partial}(\hat{\epsilon}) + \mu^w(\hat{w}, t; \hat{\epsilon}, \hat{\theta}, (f_i, \xi_i))\partial_\hat{w} \hat{V} \]  \hspace{1cm} (A.111)

s.t. \[ \int_0^1 f_i^2(\sigma_{it}^R)^2 \eta(w_{it})^{-1}di \leq \gamma_t \int_0^1 f_i \mu_{it}^R di \]  \hspace{1cm} (A.112)

Here the drift of \( \hat{w} \) conditional on controls \( c, \hat{\theta}, (f_i), \) and \( (\xi_i) \) is

\[ \mu^w(\hat{w}, t; \hat{\epsilon}, \hat{\theta}, (f_i, \xi_i)) = (r(t) + \mathbb{E}_t[\hat{\theta}d\hat{R}_t])\hat{w} - c + \int_0^1 \hat{w}_i f_i \mu_{it}^R di \]  \hspace{1cm} (A.113)

The solution for the weight on the special country’s tree \( \hat{\theta} \) will only be finite if \( \mathbb{E}_t[d\hat{R}_t] = 0 \). I will assume that this is the case henceforth. The optimal weight \( \hat{\theta}^* \) is not determined and does not
affect the value of the objective, so I will omit it from the notation for $\mu^\omega(\hat{w}, t; \hat{c}, \hat{\theta}^*, (f_i, \xi_i^*))$ below.

Guess that the value function $\hat{V}(\hat{w}, t)$ has the following form

$$\hat{V}(\hat{w}, t) = \log(\hat{\rho}(t)\hat{w}) + \hat{\kappa}(t) \tag{A.114}$$

This immediately leads to the optimal choice of consumption:

$$\hat{c}^* = \hat{\rho}(t)\hat{w} \tag{A.115}$$

Plugging this and the functional form of $\hat{\rho}(t)$ into equation (A.111),

$$\hat{\rho}(t)\hat{\kappa}(t) - \hat{\kappa}'(t) = \max_{(\hat{\theta}_i)} \int_0^1 f_i \mu_{it}^R di + r(t) - \hat{\lambda} - \hat{\rho} + \lambda\frac{w(t)}{\hat{w}(t)} \tag{A.116}$$

s.t. $\int_0^1 f_i^2(\sigma_{it}^R)^2 \eta(w_{it})^{-1} di \leq \gamma t \int_0^1 f_i \mu_{it}^R di \tag{A.117}$

Let the multiplier on the constraint be $\xi(t)$. The first-order condition for $f_i$ is

$$f_i = \eta(w_{it}) \frac{\mu_{it}^R}{(\sigma_{it}^R)^2} \cdot \frac{1 + \xi(t)\gamma(t)}{2\xi(t)} \tag{A.118}$$

Plugging this into the constraint,

$$\frac{1 - \gamma(t)^2\xi(t)^2}{4\xi(t)^2} \int_0^1 \eta(w_{it}) \left(\frac{\mu_{it}^R}{\sigma_{it}^R}\right)^2 di \leq 0 \tag{A.119}$$

This holds with equality if $\xi(t) > 0$, so $\xi(t) = 1/\gamma(t)$ and

$$f_i^* = \gamma(t)\eta(w_{it})\frac{\mu_{it}^R}{(\sigma_{it}^R)^2} \tag{A.120}$$

Plugging this back into equation (A.116),

$$\hat{\rho}(t)\hat{\kappa}(t) - \hat{\kappa}'(t) = \gamma(t) \int_0^1 \eta_{it} \left(\frac{\mu_{it}^R}{\sigma_{it}^R}\right)^2 di + r(t) - \hat{\lambda} - \hat{\rho} + \lambda\frac{w(t)}{\hat{w}(t)} \tag{A.121}$$

The only remaining bit is the suitable initial or terminal condition for $\hat{\kappa}(\cdot)$. In practice, I will use the steady state as a terminal condition as a limit at $t \to \infty$. □
F Details of equilibrium

In this section, I provide details for the equilibrium section. First, I discuss the steady state and a useful benchmark of unlimited risk-taking capacity in which there is complete risk-sharing and no non-degenerate wealth distribution. This benchmark also illustrates the role of migration between countries. Then, I provide justification for the equilibrium condition in equation (8) and equation (A.122) that decomposes intermediary’s consumption in steady state:

\[ \hat{c} = \nu \hat{q} + \nu \cdot \int \hat{h}(w)dG(w) - r \cdot \int l(w)dG(w) + \int \mu_p(w)\hat{h}(w)dG(w) \]  

\[ \hat{\lambda} = \frac{\lambda + \hat{\lambda} - \hat{\pi} - \pi}{2} \]  

I also provide a proof for Proposition 1.

Steady state. Define aggregate profit rates from risky assets \( \pi \) and \( \hat{\pi} \):

\[ \pi \int wdG(w) = \int w\theta(w)\mu_R(w)dG(w) \]  

\[ \hat{\pi} \hat{w} = \int \hat{w}f(w)\mu_R(w)dG(w) \]  

Here \( \pi \) is the average expected excess return that regular countries receive on their trees, and \( \hat{\pi} \) is the total expected excess return that the global bank receives on them. These profit rates allow me to express the steady-state interest rate and aggregate wealth of regular and special countries.

Proposition 8. In the steady state, the interest rate is

\[ r = \frac{\rho + \lambda + \hat{\rho} + \hat{\lambda} - \pi - \hat{\pi} - \sqrt{(\rho + \lambda - \hat{\rho} - \hat{\lambda} - \pi + \hat{\pi})^2 + 4\rho\hat{\lambda}}}{2} \]  

It decreases in both \( \pi \) and \( \hat{\pi} \) and is bounded between \( \min\{\rho - \pi, \hat{\rho} - \hat{\pi}\} \) and \( \max\{\rho - \pi, \hat{\rho} - \hat{\pi}\} \). The aggregate wealth of regular countries and that of the special country are given by

\[ \int wdG(w) = \frac{\hat{\lambda}(\nu + \hat{\nu})}{\rho\hat{\lambda} + \hat{\rho}\lambda + \rho\hat{\rho} - \hat{\rho}(r + \pi)} \]  

\[ \hat{w} = \frac{\hat{\lambda}(\nu + \hat{\nu})}{\rho\hat{\lambda} + \hat{\rho}\lambda + \rho\hat{\rho} - \rho(r + \hat{\pi})} \]  

This proposition shows how the interest rate and aggregate wealth of regular and special countries depend on profit rates. This is useful for thinking about the benchmark limit \( \gamma \to \infty \). In this limit, any positive expected excess returns lead the bank to assume an infinite position in risky assets. Expected excess returns \( \mu_R(w) \) then have to be zero in equilibrium, and \( \pi = \hat{\pi} = 0 \). Since \( r \) decreases in both \( \pi \) and \( \hat{\pi} \), limited risk-taking capacity depresses the global interest rate.
Holdings are well defined in this limit. Local savers are not willing to hold trees since there is fundamental risk in the dividends but expected excess returns are zero. The global bank holds all the risky assets and fully insures the regular countries. There is no wealth distribution among the regular countries because they are not exposed to idiosyncratic shocks. Equation (A.126) in this case shows wealth accumulated by each of them. Simplifying more, \( \rho = \hat{\rho} \) leads to \( r = \rho = \hat{\rho} \) and

\[
\int w dG(w) = \frac{\lambda}{\lambda + \lambda} \frac{\nu + \hat{q} \nu}{\rho}
\]

(A.128)

\[
\hat{w} = \frac{\lambda}{\lambda + \lambda} \frac{\nu + \hat{q} \nu}{\rho}
\]

(A.129)

Risk is perfectly diversified and there is no difference in time preferences, so wealth is simply the present value of output split between the intermediary and the savers by migration. This is the only way in which migration affects the aggregates. The technical reason to include it is that, without it, \( w = 0 \) would be an absorbing state for regular countries, and the special country’s income would be linear in its wealth \( \hat{w} \), leaving no possibility for a well-defined invariant distribution. In my calibration, I set net migration in the steady state to zero but allow for some gross flows.

**Proofs.** I now formulate equation (8) and equation (A.122) as propositions and prove them. I also prove Proposition 1 and Proposition 8.

Before deriving the expression for the price and quantity of risk, it is useful to rearrange the market clearing conditions for risky assets:

\[
p(w, t) = w \min \left\{ \bar{\theta}, \frac{\mu_R(w, t)}{\sigma_R(w, t)^2} \right\} + \varphi(t)\eta(w) \frac{\mu_R(w, t)}{\sigma_R(w, t)^2}
\]

(A.130)

Now I will show the equivalence between this and the price-quantity decomposition in equation (8).

**Proposition 9.** Equation (A.130) implies equation (8). That is,

\[
p(w, t) = w \min \left\{ \bar{\theta}, \frac{\mu_R(w, t)}{\sigma_R(w, t)^2} \right\} + \varphi(t)\eta(w) \frac{\mu_R(w, t)}{\sigma_R(w, t)^2} \Rightarrow
\]

(A.131)

\[
\frac{\mu_R(w, t)}{\sigma_R(w, t)^2} = \max \left\{ \frac{p(w, t)}{\varphi(t)\eta(w) + w}, \frac{p(w, t) - \bar{\theta} w}{\varphi(t)\eta(w)} \right\}
\]

(A.132)

**Proof of Proposition 9.** Suppose that equation (A.130) holds. Use the equivalence

\[
\frac{p(w, t)}{\varphi(t)\eta(w) + w} \geq \frac{p(w, t) - \bar{\theta} w}{\varphi(t)\eta(w)} \Leftrightarrow \frac{p(w, t)}{\varphi(t)\eta(w) + w} \leq \bar{\theta}
\]

(A.133)
Suppose $\mu^R(w,t)/\sigma^R(w,t)^2 \leq \overline{\theta}$. Then, from equation (A.130) it follows that
\[
\frac{\mu^R(w,t)}{\sigma^R(w,t)^2} = \frac{p(w,t)}{\varphi(t)\eta(w) + w} \tag{A.134}
\]
This means that $p(w,t)/(\varphi(t)\eta(w) + w) \leq \overline{\theta}$, so, from equation (A.133),
\[
\max\left\{ \frac{p(w,t)}{\varphi(t)\eta(w) + w}, \frac{p(w,t) - \overline{\theta}w}{\varphi(t)\eta(w)} \right\} = \frac{p(w,t)}{\varphi(t)\eta(w)} = \frac{\mu^R(w,t)}{\sigma^R(w,t)^2} \tag{A.135}
\]
Now suppose that $\mu^R(w,t)/\sigma^R(w,t)^2 > \overline{\theta}$. From equation (A.130) it follows that
\[
\frac{\mu^R(w,t)}{\sigma^R(w,t)^2} = \frac{p(w,t) - \overline{\theta}w}{\varphi(t)\eta(w)} \tag{A.136}
\]
This means that $p(w,t) - \overline{\theta}w > \overline{\theta}\varphi(t)\eta(w)$, so $p(w,t)/(w + \varphi(t)\eta(w)) > \overline{\theta}$. Then, from equation (A.133) it follows that
\[
\max\left\{ \frac{p(w,t)}{\varphi(t)\eta(w) + w}, \frac{p(w,t) - \overline{\theta}w}{\varphi(t)\eta(w)} \right\} = \frac{p(w,t) - \overline{\theta}w}{\varphi(t)\eta(w)} = \frac{\mu^R(w,t)}{\sigma^R(w,t)^2} \tag{A.137}
\]
Thus, in any case,
\[
\max\left\{ \frac{p(w,t)}{\varphi(t)\eta(w) + w}, \frac{p(w,t) - \overline{\theta}w}{\varphi(t)\eta(w)} \right\} = \mu^R(w,t) \tag{A.138}
\]
This completes the proof. □

**Proof of Proposition 1.** Start with plugging the expressions for $\mu^R(w,t)$ and $\sigma^R(w,t)$ into equation (8). Rewriting it yields a formula for the risk premium in terms of price dynamics:
\[
\frac{\mu^P(w,t) + \nu(t)}{p(w,t)} - r(t) = \frac{(\sigma^P(w,t) + \sigma)^2}{p(w,t)^2} \cdot \max\left\{ \frac{p(w,t)}{w + \varphi(t)\eta(w)}, \frac{p(w,t) - \overline{\theta}w}{\varphi(t)\eta(w)} \right\} \tag{A.139}
\]
Using Itô’s lemma,
\[
\mu^P(w,t) = \mu^w(w,t)\partial_wp(w,t) + \frac{\sigma^w(w,t)^2}{2}\partial_{ww}p(w,t) + \partial_t p(w,t) \tag{A.140}
\]
\[
\sigma^P(w,t) = \sigma^w(w,t)\partial_wp(w,t) \tag{A.141}
\]
Multiplying both sides of equation (A.139) by \( p(w, t) \),

\[
\mu^p(w, t) + \nu(t) - p(w, t)r(t) + \partial_t p(w, t) = (\sigma^p(w, t) + \sigma)^2 \cdot \max \left\{ \frac{1}{w + \varphi(t)\eta(w)}, \frac{1}{\varphi(t)\eta(w)} \left( 1 - \frac{\bar{\theta}w}{p(w, t)} \right) \right\} \quad (A.142)
\]

Plugging the drift and volatility of prices,

\[
\mu^w(w, t)\partial_w p(w, t) + \frac{\sigma^w(w, t)^2}{2} \partial_{ww} p(w, t) + \nu(t) - p(w, t)r(t) + \partial_t p(w, t) = (\sigma^w(w, t)\partial_w p(w, t) + \sigma)^2 \cdot \max \left\{ \frac{1}{w + \varphi(t)\eta(w)}, \frac{1}{\varphi(t)\eta(w)} \left( 1 - \frac{\bar{\theta}w}{p(w, t)} \right) \right\} \quad (A.143)
\]

Now rewrite the process for a regular country’s wealth in equation (A.13):

\[
dw = (r(t) - \rho)wdt + \theta(w, t)wdR(w, t) + (\lambda\hat{w}(t) - \lambda w)dt
\]

\[
= (r(t) - \rho - \lambda)wdt + \lambda\hat{w}(t)dt + w\theta(w, t)\mu^R(w, t)dt + w\theta(w, t)\sigma^R(w, t)dZ
\]

\[
= \lambda\hat{w}(t)dt + \left( r(t)(1 - \theta(w, t)) - \rho - \lambda + \theta(w, t)\frac{\mu^p(w, t) + \nu(t)}{p(w, t)} \right) wdt
\]

\[
+ w\theta(w, t)\frac{\sigma^p(w, t) + \sigma}{p(w, t)} dZ \quad (A.144)
\]

From this, it follows that

\[
\sigma^w(w, t) = w\theta(w, t)\frac{\sigma^p(w, t) + \sigma}{p(w, t)} \quad (A.145)
\]

Plugging equation (A.141),

\[
\sigma^w(w, t) = w\theta(w, t)\frac{\sigma^w(w, t)\partial_w p(w, t) + \sigma}{p(w, t)} = \frac{\theta(w, t)w\sigma}{p(w, t) - w\theta(w, t)\partial_w p(w, t)}
\]

\[
= \frac{\theta(w, t)w\sigma}{p(w, t)(1 - \theta(w, t)e(w, t))} \quad (A.146)
\]

Here \( e(w, t) = w/p(w, t) \cdot \partial_w p(w, t) \) is the wealth elasticity of the price. This implies

\[
(\sigma^w(w, t)\partial_w p(w, t) + \sigma)^2 = \left( \frac{\sigma}{1 - \theta(w, t)e(w, t)} \right)^2 \quad (A.147)
\]
Plugging this into equation (A.143),

\[
\mu^w(w,t)\partial_wp(w,t) + \frac{\sigma^w(w,t)^2}{2} \partial_{ww}p(w,t) + \nu(t) - p(w,t)r(t) + \partial_t p(w,t) = \left(\frac{\sigma}{1 - \theta(w,t)\epsilon(w,t)}\right)^2 \max \left\{ \frac{1}{w + \varphi(t)\eta(w)}, \frac{1}{\varphi(t)\eta(w)} \left(1 - \frac{\bar{\varphi}}{p(w,t)}\right) \right\}
\] (A.148)

Define the risk-adjusted payoff \(y(w,t)\) as

\[
y(w,t) = \nu(t) - \left(\frac{\sigma}{1 - \theta(w,t)\epsilon(w,t)}\right)^2 \max \left\{ \frac{1}{w + \varphi(t)\eta(w)}, \frac{1}{\varphi(t)\eta(w)} \left(1 - \frac{\bar{\varphi}}{p(w,t)}\right) \right\}
\] (A.149)

Plugging leads to

\[
r(t)p(w,t) - \partial_wp(w,t) = y(w,t) + \mu^w(w,t)\partial_wp(w,t) + \frac{\sigma^w(w,t)^2}{2} \partial_{ww}p(w,t)
\] (A.150)

This is the Kolmogorov backward equation (A.187) for prices. The Kolmogorov forward equation (A.188) for wealth follows from the fact that the wealth process is a diffusion. □

**Proof of Proposition 8.** Take the evolution of the special country’s wealth and integrate the evolution of the regular countries’ wealth to get aggregate dynamics:

\[
d\hat{w}(t) = (r(t) - \hat{\rho})\hat{w}(t)dt + \int_0^1 \hat{w}(t)f(w,t)\mu^R(w,t)dG(w,t)dt + \left(\lambda \int w\epsilon G(w,t) - \hat{\lambda}\hat{w}(t)\right) dt
\] (A.151)

\[
\int dwdG(w,t) = (r(t) - \rho) \int wdG(w,t)dt + \int w\theta(w,t)\mu^R(w,t)dG(w,t)dt + \left(\hat{\lambda}\hat{w}(t) - \lambda \int wdG(w,t)\right) dt
\] (A.152)

In the steady state, the left-hand side is zero in both of these equations:

\[
0 = (r - \hat{\rho})\hat{w} + \int_0^1 \hat{w}f(w)\mu^R(w)dG(w) + \left(\lambda \int wdG(w) - \hat{\lambda}\hat{w}\right)
\]

\[
= (r - \hat{\rho})\hat{w} + \hat{\pi}\hat{w} + \lambda \int wdG(w) - \hat{\lambda}\hat{w}
\] (A.153)

\[
0 = (r - \rho) \int wdG(w) + \int w\theta(w)\mu^R(w)dG(w) + \left(\hat{\lambda}\hat{w} - \lambda \int wdG(w)\right)
\]

\[
= (r - \rho) \int wdG(w) + \pi \int wdG(w) + \hat{\lambda}\hat{w} - \lambda \int wdG(w)
\] (A.154)
This leads to

\[ \dot{\hat{w}} = \int w dG(w) \frac{\lambda}{\lambda + \hat{\rho} - r - \hat{\pi}} = \hat{\dot{w}} \frac{\hat{\lambda}}{\lambda + \rho - r - \pi} \frac{\lambda}{\lambda + \hat{\rho} - r - \hat{\pi}} \]  

(A.155)

Reorganize this as a quadratic equation

\[ (r + \pi - \rho - \lambda)(r + \hat{\pi} - \hat{\rho} - \hat{\lambda}) = \lambda \hat{\lambda} \]  

(A.156)

The solution is

\[ r = \frac{\alpha + \hat{\alpha} \pm \sqrt{(\alpha - \hat{\alpha})^2 + 4\lambda \hat{\lambda}}}{2} \]  

(A.157)

Here \( \alpha = \rho + \lambda - \pi \) and \( \hat{\alpha} = \hat{\rho} + \hat{\lambda} - \hat{\pi} \). Take the root with a plus and consider \( r - \alpha \) and \( r - \hat{\alpha} \):

\[ r - \alpha = \frac{(\hat{\alpha} - \alpha) + \sqrt{(\hat{\alpha} - \alpha)^2 + 4\lambda \hat{\lambda}}}{2} > \hat{\alpha} - \alpha \]  

(A.158)

\[ r - \hat{\alpha} = \frac{(\alpha - \hat{\alpha}) + \sqrt{(\alpha - \hat{\alpha})^2 + 4\lambda \hat{\lambda}}}{2} > \alpha - \hat{\alpha} \]  

(A.159)

These imply that \( r > \alpha \) and \( r > \hat{\alpha} \), which is not possible since \( \dot{\hat{w}} \) and \( \int w dG(w) \) would be negative in this case. The right root is then that with a minus. Plugging this expression for the interest rate into

\[ \dot{\hat{w}} = \frac{\lambda}{\lambda + \hat{\rho} - r - \hat{\pi}} \int w dG(w) \]  

(A.160)

\[ \int w dG = \frac{\lambda}{\lambda + \rho - r - \pi} \hat{\dot{w}} \]  

(A.161)

completes the proof. □

**Proposition 10.** In the steady state,

\[ \dot{c} = \nu \hat{q} + \nu \int \hat{h}(w) dG(w) - r \cdot \int (1 - \theta(w)) w dG(w) + \int \mu^p(w) \hat{h}(w) dG(w) \]  

(A.162)

**Proof of Proposition 10** The wealth accumulation of the global bank in the steady state can be
rewritten as

\[
\begin{align*}
\hat{\dot{w}} &= (r\hat{w} - \hat{c})dt + \int f(w)\hat{\dot{w}}dR(w)dG(w) + (\lambda w - \hat{\lambda}\hat{w})dt \\
&= (r\hat{w} - \hat{c})dt - r\hat{w}dt \cdot \int f(w)dG(w) + \nu\hat{w}dt \cdot \int \hat{h}(w)dG(w) \\
&\quad + dt \cdot \int \mu^p(w)\hat{h}(w)dG(w) + (\lambda w - \hat{\lambda}\hat{w})dt
\end{align*}
\] (A.163)

This uses the fact that \(d\hat{R} = 0\) in equilibrium, so the special asset does not contribute to wealth accumulation. The second line simply applies the definition of \(d\hat{R} = (\mu^p(w) + \nu)/p(w) - r\) and the definition of \(h(w): \hat{w}f(w) = p(w)h(w)\). The balance sheet of the global bank is

\[
\hat{\dot{w}} = \int p(w)\hat{h}(w)dG(w) + \hat{\mu}q - \int (1 - \theta(w))wdG(w)
\] (A.164)

The bank’s wealth is its consolidated position in risky assets and its position in the safe asset less bonds outstanding. Plugging this and using the steady-state relations \(\hat{p} = \nu/r\) (no risk premium on the safe asset), \(d\hat{w} = 0\) (no fluctuations in the intermediary’s wealth), and \(\hat{\lambda}\hat{w} = \lambda w\) (no net migration),

\[
\hat{c} = \nu\hat{q} + \nu \cdot \int \hat{h}(w)dG(w) - r \cdot \int (1 - \theta(w))wdG(w) + \int \mu^p(w)\hat{h}(w)dG(w)
\] (A.165)

This completes the proof. \(\square\)
G Details for calibration and estimation

In this section, I explain the algorithm for calibration and estimation. I first calibrate the steady-state version of the model using four aggregate moments and a panel of external assets and liabilities from IFS data provided by the IMF. Then, I use two aggregate series and sequence-space Jacobians to estimate the parameters of aggregate shock processes by likelihood maximization.

**Calibration.** I construct the ratio of assets to liabilities:

\[ R_{it} = \frac{A_{it}}{L_{it}} \]  

(A.166)

I measure the moments of its distribution in the data using the following procedure:

- First, I take unbalanced panels for \( A_{it} \) and \( L_{it} \) starting in 1990.
- I then smooth out assets and liabilities by replacing the value in each quarter with the mean value over the last four quarters.
- For every country that eventually appears in the sample, I create a weight that is inversely proportional to the duration of its presence in the sample. This allows me to correct for the over-representation of advanced economies with relatively large assets and liabilities.

Figure A.8 shows the model fit for the distribution.

Figure A.8: Model-generated distributions (red) and data for the ratio of external assets to external liabilities.

I set the net migration flows to zero in the steady state:

\[ \lambda \int wdG(w) = \hat{\lambda} \hat{w} \]  

(A.167)
Given all other parameters, this pins down $\hat{\lambda}$. I also set $\nu = \hat{\nu}$, where $\hat{\nu}$ is the dividend rate in the special country. The level of dividends can be normalized using the following symmetry property.

Consider one model parameterized by eleven parameters $(\rho, \hat{\rho}, \lambda, \hat{\lambda}, \nu, \hat{\nu}, \sigma, \gamma, \bar{\sigma}, \bar{\gamma}, \bar{\theta}, \theta, \zeta)$ and another one parameterized by $(\rho, \hat{\rho}, \lambda, \hat{\lambda}, \nu^*, \hat{\nu}^*, \sigma^*, \gamma^*, \bar{\sigma}^*, \bar{\gamma}^*, \bar{\theta}, \theta, \zeta^*)$ such that

\[
\begin{align*}
\nu^* &= \alpha \nu, \\
\hat{\nu}^* &= \alpha \hat{\nu}, \\
\sigma^* &= \alpha \sigma, \\
\zeta^* &= \frac{\alpha \zeta}{1 + (\alpha - 1)\zeta}, \\
\gamma^* &= \gamma - \frac{(\alpha - 1)\zeta}{\alpha}.
\end{align*}
\]

The prices and quantities corresponding to the original and the starred model satisfy the following:

\[
\begin{align*}
\hat{w}^*(t) &= \alpha \hat{w}(t) \tag{A.173} \\
p^*(\alpha w, t) &= \alpha p(w, t) \tag{A.174} \\
f^*(\alpha w, t) &= f(w, t) \tag{A.175}
\end{align*}
\]

Multiplying expected dividends and their volatility by the same number simply rescales wealth and asset prices if $\gamma$ and $\zeta$ are suitably transformed. The same transformation as in equation (A.174) applies to the loadings of prices and wealth processes $(\mu_p(w, t), \mu_w(w, t), \sigma_p(w, t), \sigma_w(w, t))$, while instantaneous returns $(\mu_R(w, t), \sigma_R(w, t))$ follow the pattern in equation (A.175). Interest rates remain the same. This can be verified by noting that

\[
\varphi(t)\eta(\alpha w) = \hat{w}(t)\gamma(t)\eta + \hat{w}(t)\gamma(t)(1 - \eta) \cdot \alpha w \tag{A.176}
\]

Applying the transformations above to equation (8),

\[
\begin{align*}
\hat{w}^*(t)\gamma^*(t)\zeta^* &= \alpha \hat{w}(t)\gamma(t)\zeta \tag{A.177} \\
\hat{w}^*(t)\gamma^*(t)(1 - \zeta^*) \cdot \alpha w &= \hat{w}(t)\gamma(t)(1 - \zeta) \cdot \alpha w \tag{A.178}
\end{align*}
\]

This means

\[
\begin{align*}
\frac{\mu_R^*(\alpha w, t)}{\sigma_R^*(\alpha w, t)} &= \max \left\{ \frac{p^*(\alpha w, t)}{\varphi^*(t)\eta^*(\alpha w)} \cdot \frac{p^*(\alpha w, t) - \bar{\theta} \alpha w}{\varphi^*(t)\eta^*(\alpha w)} \right\} \tag{A.179} \\
&= \max \left\{ \frac{\alpha p(w, t)}{\alpha \varphi(t)\eta(w) + \alpha w}, \frac{\alpha p(w, t) - \bar{\theta} \alpha w}{\alpha \varphi(t)\eta(w)} \right\} = \frac{\mu_R(w, t)}{\sigma_R(w, t)} \tag{A.180}
\end{align*}
\]
Portfolio choice for αw is hence the same under the starred parameterization as that for w under the original one. The upshot is that equation (A.173) and equation (A.174) imply that $(\mu_p(w, t), \mu_w(w, t), \sigma_p(w, t), \sigma_w(w, t))$ transform in the same way as in equation (A.174), which verifies equation (A.175) since consumption follows the same proportional rule under both parametrizations and migration scales with $\dot{w}(t)$. The evolution of $\dot{w}(t)$ then shows that equation (A.173) is satisfied, and equation (A.187) shows that equation (A.174) holds.

This symmetry means that choosing a number $\nu = \hat{\nu}$ is simply a normalization. The remaining parameters are an outcome of numerical optimization, where I look for a configuration that minimizes the quadratic distance between the targets and their model analogs in Table 1. All moments are assigned the same weight.

G.1 Calibration of the model in Section 2

The model in Section 2 is a special case of the full model with $\overline{\theta} = \infty$ and $\zeta = 1$, which makes the intermediary’s weights constant: $\eta(w) = 1$ for all $w$. The special country’s tree is also not in this version of the model: $\hat{q} = 0$. Other parameters are in Table 18.

Table 18: parameters for the model is Section 2.

</table>

I choose parameters for regular countries arbitrarily and then find parameters for the special country in order to set net migration flows to zero, like in the full model. The other two targets are the interest rate of 3% annually and the US wealth share of 20%.

The average risk premium comes out to be 4 percentage points, and the average foreign ownership share for the trees is 30%.
G.2 Details of estimation

My estimation procedure relies on the mapping from sequences of shocks \( \{dW_t\} \) to the sequences of first-order deviations \( \{\tilde{m}_t, \tilde{p}_t\} \). This mapping is given by the sequence-space Jacobians calculated at the steady state and parameters \( P = (\mu_\gamma, \mu_\nu, \sigma_{\gamma_1}, \sigma_{\gamma_2}, \sigma_{\nu_2}) \). Given a potentially large sequence \( \{dW_t\} \) and a guess of \( P \), I can compute a large sequence \( \{\tilde{m}_t, \tilde{p}_t\} \) and calculate its time-series moments \( \mathcal{M}(P, \{dW_t\}) \). I can then update the guess of \( P \) to make these model-implied moments closer to \( \mathcal{M}^{\text{data}} \), the moments from the data.

Getting a point estimate for parameters consists of these steps:

- compute the targeted moments in the data \( \mathcal{M}^{\text{data}} \)
- simulate a large sequence of shocks \( \{dW(t)\} \)
- given \( \{dW(t)\} \), search over parameters \( P = (\mu_\gamma, \mu_\nu, \sigma_{\gamma_1}, \sigma_{\gamma_2}, \sigma_{\nu_2}) \) that minimize the distance between model-implied moments \( \mathcal{M}(P, \{dW(t)\}) \) and \( \mathcal{M}^{\text{data}} \)

Having obtained a point estimate \( \hat{P} = (\hat{\mu}_\gamma, \hat{\mu}_\nu, \hat{\sigma}_{\gamma_1}, \hat{\sigma}_{\gamma_2}, \hat{\sigma}_{\nu_2}) \), I use bootstrap to estimate standard errors. This procedure replaces true data with simulations created using \( \hat{P} \) and re-estimates these parameters many times. The steps are the following: for \( b \) from 1 to \( B \),

- simulate a sequence \( \{dW_t\}_b \)
- using \( \{dW_t\}_b \) and the point estimate \( \hat{P} \), compute \( \mathcal{M}^{\text{data}, b} = \mathcal{M}(\hat{P}, \{dW_t\}_b) \)
- get a point estimate \( \hat{P}_b \) by minimizing the distance between \( \mathcal{M}(P, \{dW(t)\}) \) and \( \mathcal{M}^{\text{data}, b} \) over parameters \( P \)

When this is completed \( B \) times, I have a sample of estimates \( \{\hat{P}_b\}_{b=1}^B \). I then use the standard deviations of estimates in this sample as standard errors for the original point estimates \( \hat{P} \). Figure A.9 shows point estimates and bootstrapped marginal distributions.

Figure A.9: Point estimates of parameters and the bootstrapped marginal distributions.
Quarterly magnitudes. To get a sense of magnitude for shocks to \( \gamma(t) \) and \((\nu(t), \dot{\nu}(t))\) over discrete time periods, one can solve the stochastic differential equations:

\[
\begin{align*}
\tilde{\gamma}(\tau) &= e^{-\mu_{\gamma}\tau} \tilde{\gamma}(0) + \int_0^{\tau} e^{-\mu_{\gamma}s} \sigma_{\gamma_1} dW_1(s) + \int_0^{\tau} e^{-\mu_{\gamma}s} \sigma_{\gamma_2} dW_2(s) \\
\tilde{\nu}(\tau) &= e^{-\mu_{\nu}\tau} \tilde{\nu}(0) + \int_0^{\tau} e^{-\mu_{\nu}s} \sigma_{\gamma_2} dW_2(s)
\end{align*}
\tag{A.181}
\]

Setting \( \tau = 0.25 \) yields a quarterly model and \( \tau = 1 \) makes it annual. Substituting the stochastic integrals random variables and defining parameters,

\[
\begin{align*}
\tilde{\gamma}_{t+1} &= \rho_{\gamma} \tilde{\gamma}_t + \varsigma_{\gamma_1} \epsilon_{1,t+1} + \varsigma_{\gamma_2} \epsilon_{2,t+1} \\
\tilde{\nu}_{t+1} &= \rho_{\nu} \tilde{\nu}_t + \varsigma_{\nu_2} \epsilon_{2,t+1}
\end{align*}
\tag{A.182}
\]

Here the persistence parameters are \( \rho_{\gamma} = e^{-\mu_{\gamma}\tau} \), \( \rho_{\nu} = e^{-\mu_{\nu}\tau} \), random variables \((\epsilon_{1,t+1}, \epsilon_{2,t+1})\) are independent standard normals, and the volatilities of innovations are

\[
\varsigma_{\gamma_1} = \sigma_{\gamma_1} \sqrt{\mathbb{E} \left[ \int_0^{\tau} e^{-\mu_{\gamma}s} dW_1(s) \right]} = \sigma_{\gamma_1} \sqrt{\mathbb{E} \left[ \int_0^{\tau} e^{-2\mu_{\gamma}s} ds \right]} = \sigma_{\gamma_1} \sqrt{\frac{1 - e^{-2\mu_{\gamma}\tau}}{2\mu_{\gamma}}} \tag{A.184}
\]

Similarly,

\[
\begin{align*}
\varsigma_{\gamma_2} &= \sigma_{\gamma_2} \sqrt{\frac{1 - e^{-2\mu_{\gamma}\tau}}{2\mu_{\gamma}}} \\
\varsigma_{\nu_2} &= \sigma_{\nu_2} \sqrt{\frac{1 - e^{-2\mu_{\nu}\tau}}{2\mu_{\nu}}} \tag{A.185}
\end{align*}
\]

It is more natural to report these parameters as a share of the steady-state values \( \gamma \) and \( \nu \). Table 19 reports them for the quarterly and annual frequencies.

<table>
<thead>
<tr>
<th></th>
<th>( \rho_{\gamma} )</th>

</tr>
</tbody>
</table>

The correlation between innovations to \( \tilde{\gamma}_{t+1} \) and \( \tilde{\nu}_{t+1} \) is 0.56 at all horizons.
H Numerical solution algorithm

Here I briefly describe the algorithm I use to solve the system of partial differential equations in Proposition 1. The system is for prices $p(w, t)$ and density $g(w, t)$:

$$r(t)p(w, t) - \partial_t p(w, t) = y(w, t) + \mu_w(w, t)\partial_w p(w, t) + \frac{1}{2}\sigma_w(w, t)^2\partial_{ww} p(w, t)$$  \hspace{1cm} (A.187)

$$\partial_t g(w, t) = -\partial_w[\mu_w(w, t)g(w, t)] + \frac{1}{2}\partial_{ww} [\sigma_w(w, t)^2 p(w, t)]$$  \hspace{1cm} (A.188)

Here the function $y(w, t)$ is the risk-adjusted payoff:

$$y(w, t) = \nu(t) - \left(1 - \frac{\sigma}{1 - \epsilon(w, t)\theta(w, t)}\right)^2 \max \left\{\frac{1}{w + \varphi(t)\eta(w)}, \frac{1}{\varphi(t)\eta(w)}\left(1 - \frac{\theta w}{p(w, t)}\right)\right\}$$  \hspace{1cm} (A.189)

with $\epsilon(w, t) = w/p(w, t) \cdot \partial_w p(w, t)$ being the wealth elasticity of price.

The partial differential equation (A.187) is non-linear. The price $p(w, t)$ is explicitly included in $y(w, t)$. Moreover, the drift and volatility of wealth $\mu_w(w, t)$ and $\sigma_w(w, t)$ depend on it. Plugging the optimal policy of investors,

$$\mu_w(w, t) = (r(t) - \rho - \lambda)w + \hat{\lambda}w(t) + \min \left\{\frac{\mu_R(w, t)}{\sigma_R(w, t)^2, \theta} \mu_R(w, t)w\right\}$$  \hspace{1cm} (A.190)

$$\sigma_w(w, t) = \min \left\{\frac{\mu_R(w, t)}{\sigma_R(w, t)^2, \theta} \sigma_R(w, t)w\right\}$$  \hspace{1cm} (A.191)

Here the mean and volatility of returns are

$$\mu_R(w, t) = \frac{\mu_p(w, t) + \nu(t)}{p(w, t)} - r(t)$$  \hspace{1cm} (A.192)

$$\sigma_R(w, t) = \frac{\sigma_p(w, t) + \sigma}{p(w, t)}$$  \hspace{1cm} (A.193)

The drift and volatility of prices, $\mu_p(w, t)$ and $\sigma_p(w, t)$, in turn can be expressed in terms of $\mu_w(w, t)$ and $\sigma_w(w, t)$ using Itô’s lemma:

$$\mu_p(w, t) = \partial_t p(w, t) + \mu_w(w, t)\partial_w p(w, t) + \frac{\sigma_w(w, t)^2}{2}\partial_{ww} p(w, t)$$  \hspace{1cm} (A.194)

$$\sigma_p(w, t) = \sigma_w(w, t)\partial_w p(w, t)$$  \hspace{1cm} (A.195)

I next describe the iterative algorithm that I use to solve for $p(w, t)$ as a fixed point of equation (A.187). I first describe the steady state, where all functions just have $w$ as their argument, and both equation (A.187) and equation (A.188) are ODE, not PDE. After that, I describe the transition dynamics.
My numerical solution requires a discretization of time and wealth spaces. In addition, I use a monotone transformation of the wealth scale from $[0, \infty)$ onto $[0, 1]$ by mapping $w$ to another function $x(w) = 1 - e^{-w}$. This allows for better approximations at large levels of wealth, which is useful given that one of the boundary conditions for $p(w, t)$ is at infinity. All equations have to be corrected for this transformation using the chain rule and Itô’s lemma.

**Steady state.** To compute the price functions in the steady state, I use a two-tier loop. In the outer loop, I solve for $r$, $\hat{w}$, and $G(\cdot)$, the distribution of $w$ that produce all other quantities that clear markets. In the inner loop, I fix $r$, $\hat{w}$, and $\varphi = \gamma \hat{w}$ and solve for prices. Given these numbers, I iterate on the price functions in the following way:

- guess $p^{(n)}(w)$, $\mu^{(n)}_w(w)$, and $\sigma^{(n)}_w(w)$
- compute $y(w)$ and solve the time-invariant version of equation (A.187), which is on ODE instead of a PDE in the steady state, to get the new guess $p^{(n+1)}(w)$
- use the new guess $p^{(n+1)}(w)$ and old guesses $\mu^{(n)}_w(w)$ and $\sigma^{(n)}_w(w)$ in equation (A.194) and equation (A.195) get $\mu_p(w)$ and $\sigma_p(w)$
- use the new guess $p^{(n+1)}(w)$ and the newly computed $\mu_p(w)$ and $\sigma_p(w)$ to compute $\mu_R(w)$ and $\sigma_R(w)$, the mean and standard deviation of excess returns in equation (A.192) and equation (A.193)
- use the newly computed $\mu_R(w)$ and $\sigma_R(w)$ to compute the new guesses $\mu^{(n+1)}_w(w)$ and $\sigma^{(n+1)}_w(w)$ of the drift and volatility of wealth in equation (A.190) and equation (A.191)
- stop if old and new guesses from $p(w)$, $\mu_w(w)$, and $\sigma_w(w)$ are sufficiently close

In the outer loop, I use the last guesses for $\mu_w(w)$ and $\sigma_w(w)$ to solve equation (A.188). This allows me to compute the steady-state value of the average regular country wealth $\int wdG(w)$ and the total profits of the intermediary, which also takes in the last guess of $\mu_R(w)$. I then compute the steady-state value of $\hat{w}$ using the fact that wealth accumulation in the special country is zero: consumption $\hat{w}$ offsets profits, and net migration is zero. Given the new guess for $\hat{w}$, I compute the new guess for $r$ using the intermediary’s balance sheet:

$$\hat{w} = \frac{\nu}{r} \hat{q} + \int p(w) h(w) dG(w) - \int l(w) dG(w) \quad (A.196)$$

Here the ratio $\nu/r$ is the steady-state price of the safe asset.

**Transition dynamics.** I discretize the time and solve for sequences of $r(t)$ and $\hat{w}(t)$. Given guesses for these sequences, I also have a guess for the sequence $\varphi(t)$. 

41
There is an inner loop at all nodes $t$ of the time grid where I solve for the current price vector $p(w,t)$ and the vectors of wealth drift and volatilities $\mu_w(w,t)$ and $\sigma_w(w,t)$. This inner loop is exactly the same as in solving for the steady state price.

In the outer loop, I compute the flow profits of all investors, the evolution of wealth in all countries, and migration flows using $(\mu_p(w,t), \sigma_p(w,t), \mu_R(w,t), \sigma_R(w,t), \mu_w(w,t), \sigma_w(w,t))_{t \geq 0}$. This calculation leads to the new guess of the path of the special country’s wealth $(\hat{w}(t))_{t \geq 0}$ and the global factor $(\varphi(t))_{t \geq 0}$. The new guess of the interest rate sequence $(r(t))_{t \geq 0}$ comes from differentiating the consumption goods market clearing condition with respect to time:

$$\rho \int \mu_w(w,t)dG(w,t) + \hat{\rho}\hat{\mu}'(t) = \nu'(t) + \hat{\nu}'(t)$$  \hspace{1cm} (A.197)

The interest rate can be extracted from this equation given profit flows coming from expected excess returns $\mu_R(w,t)$. I then use the sequence space Jacobians to update the guesses.
Details for impulse responses

The decomposition of the impact response of asset prices relies on the following fact. It is enough to know the future path of dividends \((\nu(t))_{t \geq 0}\), the interest rate \((r(t))_{t \geq 0}\), the global factor \((\phi(t))_{t \geq 0}\), and the intermediary’s wealth \((\hat{w}(t))_{t \geq 0}\) to calculate the whole path of \((p(w, t))_{t \geq 0}\). The intermediary’s wealth only matters for migration flows, given the path of \((\phi(t))_{t \geq 0}\).

Taking advantage of this, I produce decompositions on Figure 6 and Figure 9. First, for the shock to risk-taking capacity, I compute two counterfactual price sequences: one with \(r(t)\) set at the steady-state \(r\) (this isolates the effect of \(\phi(t)\)), and the other with \(\phi(t)\) set at the steady-state \(\phi\), isolates the effect of \(r(t)\). In both cases, all other sequences are taken from the baseline general equilibrium transition dynamics.

For the output shock, I compute three counterfactual price sequences. One is with \(r(t)\) and \(\phi(t)\) both held at the steady-state levels. This isolates the effect of \(\nu(t)\) that directly enters the Kolmogorov backward equation for prices. Another holds \(r(t)\) and \(\nu(t)\) at the steady-state level, isolating the effect of \(\phi(t)\), and the last one isolates the effect of \(r(t)\) by taking in constant \((\nu, \phi)\).

These decompositions are not additive, since I consider relatively large shocks, and prices are highly non-linear in \(r(t), \phi(t), \nu(t)\).

Expectations in cross-section. Panel (a) on Figure 8 provides cross-sections of expected holdings at three different points in time, \(t = 0, t = 0.25,\) and \(t = 1,\) conditional on \(w_0\). The value of holdings at \(t = 0\) conditional on \(w_0\). Holdings as a function of \((w, t)\) are known too. But wealth itself changes between \(t = 0\) and \(t = 0.25\), both due to aggregate drift and idiosyncratic shocks.

Consider any function \(z(w, t)\). The time-\(s\) expectation at time \(t\), denoted by \(Z(w, t, s)\), is

\[
Z(w, t, s) = \mathbb{E}_t \left[ z(w_s, s) \middle| w_t = w \right]
\]  \hspace{1cm} (A.198)

This object satisfies the following HJB equation:

\[
0 = \partial_t Z(w, t, s) + \mu_w(w, t) \partial_w Z(w, t, s) + \frac{\sigma_w(w, t)^2}{2} \partial_{ww} Z(w, t, s)
\]  \hspace{1cm} (A.199)

The terminal condition is \(Z(w, s, s) = z(w, s)\). I compute holdings of domestic assets \(\tau\) ahead expected at \(t = 0\) by solving this partial differential equation numerically and evaluating \(Z(w, 0, \tau)\).

Another type of cross-section of expectations is an expected average over time. Panel (b) on Figure 8 shows the cross-section of expected wealth accumulation over the first quarter, decomposing it into parts. These expectations can be computed as follows. Take any time-varying function \(\tilde{z}(w, t)\). The expected time average between \(t\) and \(s\) conditional on \(w_t\), denoted by \(\tilde{Z}(w, t, s)\), is

\[
\tilde{Z}(w, t, s) = \mathbb{E}_t \left[ \int_t^s \tilde{z}(w, \tau) d\tau \middle| w_t = w \right]
\]  \hspace{1cm} (A.200)
This object satisfies the following HJB equation:

\[ 0 = \ddot{z}(w, t) - \partial_s \tilde{Z}(w, t, s) + \mu_w(w, t) \partial_w \tilde{Z}(w, t, s) + \frac{\sigma_w(w, t)^2}{2} \partial_{ww} \tilde{Z}(w, t, s) \]  

\( (A.201) \)

The terminal condition is \( \tilde{Z}(w, s, s) = 0 \). I evaluate \( \tilde{Z}(w, 0, \tau) \) for panel (b) on Figure 8.

Note that the expectation functions \( Z(w, t, s) \) is essentially nested in \( \tilde{Z}(w, t, s) \) if one is willing to consider the function \( z(w, t) \) that incorporates Dirac’s delta function:

\[ \ddot{z}(w, t) = \delta(t - s) z(w, t) \]  

\( (A.202) \)

Importantly, when plotting panel (a) and panel (b) on Figure 8, I account for initial wealth revaluation. Specifically, instead of \( Z(w, 0, \tau) \) and \( \tilde{Z}(w, 0, \tau) \), I plot \( Z(W(w), 0, \tau) \) and \( \tilde{Z}(W(w), 0, \tau) \), where the function \( W(\cdot) \) maps wealth just before the shock hits into the level after revaluation.

**Revaluation.** Wealth revaluation in regular countries happens because asset prices jump on impact. The function \( W(\cdot) \) solves the following functional equation:

\[ W(w) = b(w) + p(W(w), 0) h(w) \]  

\( (A.203) \)

After revaluation, wealth consists of the old, steady-state level of deposits \( l(w) \) and old holdings of risky assets \( h(w) \) evaluated at the new price \( p(W(w), 0) \). The holdings have to be taken from just before the shock since revaluation happens before portfolios can be rebalanced. The absence of \( t \) as an argument in \( h(w) \) and \( l(w) \) means that these are steady-state functions. The price is evaluated at \( W(w) \) since the country instantly becomes one with wealth \( W(w) \) instead of \( w \).

Wealth revaluation thus comes from two sources. First, price as a function of wealth changes relative to the steady state: \( p(w, 0) \neq p(w) \). Second, wealth itself changes because changing prices revalue it: \( W(w) \neq w \). In my numerical procedure, I solve for \( W(w) \) given \( p(\cdot) \) as a function of \( (w, t) \) by iterating on guesses \( W^n(\cdot) \):

\[ W^{n+1}(w) = b(w) + p(W^n(w), 0) h(w) \]  

\( (A.204) \)

I evaluate the new guess \( W^{n+1}(\cdot) \) on the grid by interpolation and do it until convergence.
J  Additional details for shocks

This section provides additional details for the shock to risk-taking capacity of the intermediaries and the output shock.

Adjustment to the risk-taking capacity shock in the special country. The special country’s net foreign assets position (NFA) falls on impact because of the losses it makes on its risky portfolio. Panel (a) on Figure A.10 shows the path of NFA over the special country’s GDP over time after the shock to $\gamma$.

![Figure A.10: Responses of the special country’s NFA and components of net income, percent of GDP. Panel (a): change in NFA decomposed into price changes and net assets accumulation. Panel (b): changes in dividends from regular countries, interest payments to them, and asset prices.](image)

The evolution after $t = 0$ is due to changes in asset prices and accumulation of assets net of incurrence of liabilities. The capital gains component $k(t)$ is given by $k(0) < 0$ and

$$\dot{k}(t) = \int \mu_p(w, t)\hat{h}(w, t)dG(w, t) - \int \mu_p(w)\hat{h}(w)dG(w)$$

The subtracted term corresponds to the steady state. Capital gains start off negative at $t = 0$, reflecting the losses made on impact. NFA then reverses, and valuation changes contribute to it.

Asset accumulation accounts for purchases of shares in risky assets that do not result in additional deposits made by regular countries. Panel (b) sheds light on the sources of these purchases. It plots the changes in four components of the intermediary’s wealth accumulation: dividends from assets in regular countries, interest payments (this component contributes negatively to net income), capital gains on risky assets, and capital gains on the safe asset.

Interest payments to regular countries decline by more than dividends flowing out of those countries. The intermediary uses this difference to buy back the shares that local investors in rich countries purchased on impact while retrenching. Changes in consumption are much smaller in magnitude, so almost all of this extra income goes to financing asset purchases. Dividends from
the safe asset remain constant and are not shown in the picture. Capital gains on risky assets are positive, and those on the safe asset are negative as prices revert back to normal.

**Shock to output.** Figure A.11 and Figure A.12 show density-weighted losses made on assets as a percentage of global GDP. The distributions are remarkably similar. Losses on risky assets are shared between regular countries and the intermediary in roughly the same proportions after both shocks, and the fall in the safe asset price $\hat{p}(t)$ is only marginally larger (relative to other assets) when its dividends are hit.

This shows how important the global intermediary is for risk-sharing. Even though it is the only owner of the safe asset, the fall in the safe asset’s dividends has largely the same consequences for the global wealth distribution as a shock to $\nu$, adjusting for size. The intermediary’s exposure to risky assets generates contagion. This force is the reverse side of insurance that it provides to other countries by absorbing a part of their losses.

Figure A.11: Shock to $\nu$ in regular countries: gains and losses on of the intermediary and local savers on impact (percent of global GDP, weighted by density)

Figure A.12: Shock to $\nu$ in special country: gains and losses on of the intermediary and local savers on impact (percent of global GDP, weighted by density)

Table 20: Shock to $\nu$ in regular countries: gains on impact (percent of global GDP). Low $w$ countries are those constrained in steady state, $\theta(w) = \bar{\theta}$

Table 22 collects the differences between the shocks to $\gamma$ and $\nu$. The shock to the global intermediary’s risk-taking capacity is essential to generate large capital flows on impact, and these flows only happen in deep markets with rich and unconstrained domestic investors. The shock to output is essential to generate a fall in asset prices that is not confined to poor countries with a
shallow investor base. The safe asset appreciates when the intermediary loses appetite for risk and depreciates when the interest rate rises to accommodate a fall in production.

Details for linearization

In this section, I explain the linearization procedure. The notation convention is that a function \( z(w) \) with only one argument corresponds to the steady state. Functions with tildes, like \( \tilde{z}(w, t) \), correspond to the first-order deviations.

**Step 1: constraint is slack.** Take values of \( w \) for which the constraint is slack in the steady state. Start with the drift and volatility of the wealth:

\[
\mu_w(w, t) = (r(t) - \rho - \lambda)w + \hat{\lambda}n(t) + \mu_R(w, t)\theta(w, t)w
\]

\[
\sigma_w(w, t) = \sqrt{\sigma_R(w, t)\theta(w, t)w}
\]  

(A.205)  

(A.206)

Using the optimal choice, \( \theta(w, t) = \mu_R(w, t)/\sigma_R(w, t) \), replace the returns in the drift:

\[
\mu_w(w, t) = (r(t) - \rho - \lambda)w + \hat{\lambda}n(t) + \frac{\sigma_w(w, t)^2}{w}
\]  

(A.207)

This leads to

\[
\bar{\mu}_w(w, t) = w\tilde{r}(t) + \hat{\lambda}\tilde{n}(t) + \frac{2\sigma_w(w)}{w}\tilde{\sigma}_w(w, t)
\]

(A.208)

Now using the definition \( \sqrt{\sigma_R(w, t)} = (\sigma_p(w, t) + \sigma_y)/p(w, t) \) and \( \sigma_p(w, t) = \partial_\phi p(w, t)\sigma_w(w, t) \),

\[
\sigma_w(w, t) = \frac{\sigma_y\theta(w, t)w}{p(w, t) - \theta(w, t)\partial_\phi p(w, t)w}
\]  

(A.209)

Using market clearing \( \mu_R(w, t)/\sigma_R(w, t) = p(w, t)/(\varphi(t)\eta(w) + w) \) and \( \theta(w, t) = \mu_R(w, t)/\sigma_R(w, t) \),

\[
\sigma_w(w, t) = \frac{\sigma_yw}{\varphi(t)\eta(w) + w - \partial_\phi p(w, t)w}
\]  

(A.210)

Expanding,

\[
\tilde{\sigma}_w = \frac{\sigma_w(w)^2}{\sigma_yw}(w\partial_\phi \tilde{p} - \eta(w)\tilde{\varphi}(t))
\]

(A.211)

The market-clearing condition is

\[
\mu_p(w, t) + \nu - r(t)p(w, t) = (\sigma_p(w, t) + \sigma_y)^2 \frac{1}{\varphi(t)\eta(w) + w}
\]

(A.212)
Expanding,

$$\tilde{\mu}_p - \tilde{r}(t)p(w) - r\tilde{p} = \tilde{\sigma}_p \frac{2(\sigma_p(w) + \sigma_y)}{\varphi(t)\eta(w) + w} - \tilde{\varphi}(t)\eta(w) \frac{(\sigma_p(w) + \sigma_y)^2}{(\varphi(t)\eta(w) + w)^2}$$  \hspace{1cm} (A.213) \]

Now using $\sigma_w(w) = w\theta(w)(\sigma_p(w) + \sigma_y)/p(w) = w(\sigma_p(w) + \sigma_y)/\eta(w) + w$,

$$\tilde{\mu}_p = \tilde{\sigma}_p \frac{2\sigma_w(w)}{w} - r\tilde{p} = \tilde{r}(t)p(w) - \tilde{\varphi}(t)\eta(w) \frac{\sigma_w(w)^2}{w^2}$$  \hspace{1cm} (A.214) \]

The expressions for $\tilde{\mu}_p$ and $\tilde{\sigma}_p$ are

$$\tilde{\mu}_p = \partial_t\tilde{\mu} + \mu_w(w)\partial_w\tilde{\mu} + p'(w)\tilde{\mu}_w + \tilde{\sigma}_w\sigma_w(w)p''(w) + \frac{\sigma_w(w)^2}{2}\partial_{ww}\tilde{\mu}$$  \hspace{1cm} (A.215) \]

$$\tilde{\sigma}_p = \partial_w\tilde{\mu}\sigma_w(w) + p'(w)\tilde{\sigma}_w$$  \hspace{1cm} (A.216) \]

Combining,

$$\tilde{\mu}_p - \tilde{\sigma}_p \frac{2\sigma_w(w)}{w} = p'(w)(w\tilde{r}(t) + \hat{\lambda}\hat{n}(t)) + \partial_t\tilde{\mu} + \frac{\sigma_w(w)^2}{2}\partial_{ww}\tilde{\mu} + \left(\mu_w(w) - \frac{2\sigma_w(w)^2}{w}\right)\partial_w\tilde{\mu}$$

$$+ \tilde{\sigma}_w\sigma_w(w)p''(w)$$

$$= p'(w)(w\tilde{r}(t) + \hat{\lambda}\hat{n}(t)) - \tilde{\varphi}(t)p''(w)\frac{\sigma_w(w)^3\eta(w)}{\sigma_yw}$$

$$+ \partial_t\tilde{\mu} + \frac{\sigma_w(w)^2}{2}\partial_{ww}\tilde{\mu} + \left(\mu_w(w) - \frac{2\sigma_w(w)^2}{w} + p''(w)\frac{\sigma_w(w)^3}{\sigma_y}\right)\partial_w\tilde{\mu}$$  \hspace{1cm} (A.217) \]

Plugging this into equation (A.214),

$$\frac{\sigma_w(w)^2}{2}\partial_{ww}\tilde{\mu} + \left(\mu_w(w) - \frac{2\sigma_w(w)^2}{w} + p''(w)\frac{\sigma_w(w)^3}{\sigma_y}\right)\partial_w\tilde{\mu} - r\tilde{p} = \tilde{r}(t)(p(w) - p'(w)w) - p'(w)\lambda\hat{n}(t)$$

$$+ \left(p''(w)\frac{\sigma_w(w)^3\eta(w)}{\sigma_yw} - \eta(w)\frac{\sigma_w(w)^2}{w^2}\right)\tilde{\varphi}(t) - \partial_t\tilde{\mu}$$  \hspace{1cm} (A.218) \]

**Step 2: the constraint binds.** Take values of $w$ for which the constraint binds in the steady state. The drift and volatility of the wealth are

$$\mu_w(w, t) = (r(t) - \rho - \lambda)w + \hat{\lambda}\hat{n}(t) + \mu_R(w, t)\theta w$$  \hspace{1cm} (A.219) \]

$$\sigma_w(w, t) = \theta \sqrt{\sigma_R(w, t)w}$$  \hspace{1cm} (A.220) \]
Using market clearing $\mu_R(w, t)/\sigma_R(w, t) = (p(w, t) - \bar{\theta} w)/(\varphi(t) \eta(w))$ and the definition of $\sigma_R(w, t)$,

$$
\mu_w(w, t) = (r(t) - \rho - \lambda) w + \lambda n(t) + \frac{\sigma_w(w, t)^2}{\varphi(t) \eta(w)} \left( \frac{p(w, t)}{\bar{\theta} w} - 1 \right) \\
\sigma_w(w, t) = \frac{\bar{\theta} w \sigma_y}{p(w, t) - \bar{\theta} w \sigma_y p(w, t)}
$$

Expanding,

$$
\tilde{\mu}_w = \tilde{r}(t) w + \hat{\lambda} n(t) - \frac{\sigma_w(w)^2}{\varphi^2 \eta(w)} \left( \frac{p(w, t)}{\bar{\theta} w} - 1 \right) \tilde{\varphi}(t) \\
+ \frac{2 \sigma_w(w)}{\varphi \eta(w)} \left( \frac{p(w, t)}{\bar{\theta} w} - 1 \right) \tilde{\sigma}_w + \frac{\sigma_w(w)^2}{\varphi \bar{\theta} \eta(w) w} \tilde{p} \\
\tilde{\sigma}_w = \frac{\sigma_w(w)^2}{\sigma_y} \tilde{\partial}_w \tilde{p} - \frac{\sigma_w(w)^2}{\bar{\theta} w \sigma_y} \tilde{p}
$$

The expressions for expanded drift and volatility of the price process are

$$
\tilde{\mu}_p = \partial_t \tilde{p} + \mu_w(w) \partial_w \tilde{p} + p'(w) \tilde{\mu}_w + \sigma_w(w) p''(w) + \frac{\sigma_w(w)^2}{2} \partial_{ww} \tilde{p} \\
= \partial_t \tilde{p} + \frac{\sigma_w(w)^2}{2} \partial_{ww} \tilde{p} + \mu_w \partial_w \tilde{p} + p'(w) \left( w \tilde{r}(t) + \hat{\lambda} n(t) - \frac{\sigma_w(w)^2}{\varphi^2 \eta(w)} \left( \frac{p(w, t)}{\bar{\theta} w} - 1 \right) \tilde{\varphi}(t) \right) \\
+ p'(w) \left( \frac{2 \sigma_w(w)}{\varphi \eta(w)} \left( \frac{p(w, t)}{\bar{\theta} w} - 1 \right) \tilde{\sigma}_w + \frac{\sigma_w(w)^2}{\varphi \bar{\theta} \eta(w) w} \tilde{p} \right) + p''(w) \sigma_w(w) \tilde{\sigma}_w
$$

$$
\tilde{\sigma}_p = \sigma_w(w) \partial_w \tilde{p} + p'(w) \tilde{\sigma}_w
$$

The market clearing condition is

$$
\mu_p(w, t) + y - r(t) p(w, t) = (\sigma_p(w, t) + \sigma_y)^2 \frac{1}{\varphi(t) \eta(w)} \left( 1 - \frac{\bar{\theta} w}{p(w, t)} \right)
$$

Expanding,

$$
\tilde{\mu}_p - p(w) \tilde{r}(t) - r \tilde{p} = 2 \tilde{\sigma}_p \frac{\sigma_p(w) + \sigma_y}{\varphi \eta(w)} \left( 1 - \frac{\bar{\theta} w}{p(w)} \right) - \frac{(\sigma_p(w) + \sigma_y)^2}{\varphi^2 \eta(w)} \left( 1 - \frac{\bar{\theta} w}{p(w)} \right) \tilde{\varphi}(t) \\
+ \frac{(\sigma_p(w) + \sigma_y)^2}{\varphi \eta(w)} \frac{\bar{\theta} w}{p(w)^2} \tilde{p}
$$
Now using $\sigma_p(w) + \sigma_y = \sigma_w(w)p(w)/(\bar{\vartheta}w)$,
\[
\tilde{\mu}_p - p(w)\tilde{r}(t) - r\tilde{p} = \tilde{\sigma}_p \frac{2\sigma_w(w)}{\varphi\eta(w)} \left( \frac{p(w)}{\vartheta w} - 1 \right) - \frac{\sigma_w(w)p(w)}{\varphi^2\bar{\vartheta}w(w)w} \left( \frac{p(w)}{\vartheta w} - 1 \right) \tilde{\varphi}(t)
+ \frac{\sigma_w(w)^2}{\varphi\bar{\vartheta}\eta(w)w} \tilde{p}
\]
(A.229)

Now compute
\[
\tilde{\mu}_p - \tilde{\sigma}_p \frac{2\sigma_w(w)}{\varphi\eta(w)} \left( \frac{p(w)}{\vartheta w} - 1 \right) = \partial_t \tilde{p} + \frac{\sigma_w(w)^2}{2} \partial_{ww} \tilde{p} + \mu_w \partial_w \tilde{p}
+ p'(w) \left( w\tilde{r}(t) + \hat{\lambda}\tilde{n}(t) - \frac{\sigma_w(w)^2}{\varphi^2\eta(w)} \left( \frac{p(w, t)}{\vartheta w} - 1 \right) \tilde{\varphi}(t) \right)
- \frac{2\sigma_w(w)^2}{\varphi\eta(w)} \left( \frac{p(w)}{\vartheta w} - 1 \right) \partial_w \tilde{p} + \frac{\sigma_w(w)^2}{\varphi\bar{\vartheta}\eta(w)w} \tilde{p} + p''(w)\sigma_w(w)\tilde{\sigma}_w
= \partial_t \tilde{p} + \frac{\sigma_w(w)^2}{2} \partial_{ww} \tilde{p}
+ \left( \mu_w - \frac{2\sigma_w(w)^2}{\varphi\eta(w)} \left( \frac{p(w)}{\vartheta w} - 1 \right) + \frac{p''(w)\sigma_w(w)^3}{\sigma_y} \right) \partial_w \tilde{p}
+ p'(w) \left( w\tilde{r}(t) + \hat{\lambda}\tilde{n}(t) - \frac{\sigma_w(w)^2}{\varphi^2\eta(w)} \left( \frac{p(w, t)}{\vartheta w} - 1 \right) \tilde{\varphi}(t) \right)
+ \left( \frac{p'(w)\sigma_w(w)^2}{\varphi\bar{\vartheta}\eta(w)w} - \frac{p''(w)\sigma_w(w)^3}{\vartheta w\sigma_y} \right) \tilde{p}
\]
(A.230)

Plugging,
\[
\partial_t \tilde{p} + \partial_{ww} \tilde{p} \frac{\sigma_w(w)^2}{2} + \partial_w \tilde{p} \left( \mu_w(w) + \frac{\sigma_w(w)^3}{\sigma_y} p''(w) - \frac{2\sigma_w(w)^2}{\varphi\eta(w)} \left( \frac{p(w)}{\vartheta w} - 1 \right) \right)
+ \tilde{p} \left( \frac{\sigma_w(w)^2(p'(w) - 1)}{\varphi\bar{\vartheta}\eta(w)w} - \frac{\sigma_w(w)^3p''(w)}{\vartheta w\sigma_y} \right)
= (p(w) - p'(w)w)\tilde{r}(t) - p'(w)\hat{\lambda}\tilde{n}(t) - \frac{\sigma_w(w)^2}{\varphi^2\eta(w)} \left( \frac{p(w)}{\vartheta w} - 1 \right) \left( \frac{p(w)}{\vartheta w} - p'(w) \right) \tilde{\varphi}(t)
\]
(A.231)

Finally, acknowledging that $p(w)/(\bar{\vartheta}w) - p'(w) = \sigma_y/\sigma_w(w)$,
\[
\partial_t \tilde{p} + \frac{\sigma_w(w)^2}{2} \partial_{ww} \tilde{p} + \left( \mu_w(w) + \frac{p''(w)\sigma_w(w)^3}{\sigma_y} - \frac{2\sigma_w(w)^2}{\varphi\eta(w)} \left( \frac{p(w)}{\vartheta w} - 1 \right) \right) \partial_w \tilde{p}
+ \tilde{p} \left( \frac{\sigma_w(w)^2(p'(w) - 1)}{\varphi\bar{\vartheta}\eta(w)w} - \frac{\sigma_w(w)^3p''(w)}{\vartheta w\sigma_y} \right)
= \tilde{r}(t)(p(w) - p'(w)w) - p'(w)\hat{\lambda}\tilde{n}(t) - \frac{\sigma_w(w)\sigma_y}{\varphi^2\eta(w)} \left( \frac{p(w)}{\vartheta w} - 1 \right) \tilde{\varphi}(t)
\]
(A.232)
Step 3: putting it together. Now rewrite the equations together. When the constraint is slack,\begin{equation}
\partial_t \tilde{p} + \frac{\sigma_w(w)^2}{2} \partial_{ww} \tilde{p} + \left( \mu_w(w) + p''(w) \frac{\sigma_w(w)^3}{\sigma_y w} - \frac{2\sigma_w(w)^2}{w} \right) \partial_w \tilde{p} - r \tilde{p} = \tilde{r}(t)(p(w) - p'(w)w) - p'(w)\tilde{n}(t) + \left( p''(w) \frac{\sigma_w(w)^3 \eta(w)}{\sigma_y w} - \frac{\sigma_w(w)^2 \eta(w)}{w^2} \right) \tilde{\varphi}(t) \quad (A.233)
\end{equation}

When it binds:\begin{equation}
\begin{split}
\partial_t \tilde{p} + \frac{\sigma_w(w)^2}{2} \partial_{ww} \tilde{p} + & \left( \mu_w(w) + p''(w) \frac{\sigma_w(w)^3}{\sigma_y w} - \frac{2\sigma_w(w)^2}{w} \right) \frac{(p(w) + \varphi \eta(w))}{\partial_w \sigma_y} - r \tilde{p} \\
+ & \tilde{p} \left( \frac{\sigma_w(w)^2}{\varphi \eta(w)} \frac{(p'(w) - 1)}{\eta(w)} - \frac{\sigma_w(w)^3 p''(w)}{\varphi^2 \eta(w)} - r \right) \tilde{\varphi}(t)
\end{split}
\quad (A.234)
\end{equation}

At the boundary $\overline{w}$,\begin{equation}
\lim_{w \to \overline{w} + 0} \frac{1}{\varphi \eta(w)} \left( \frac{p(w)}{\eta(w)} - w \right) = 1 \quad (A.235)
\end{equation}

The coefficient on $\partial_w \tilde{p}$ is continuous. Subtracting the $\overline{w}+$ and $\overline{w}-$ limits of A.233 and A.234,\begin{equation}
\begin{split}
\frac{\sigma_w(\overline{w})^2}{2} \left( \partial_{ww} \tilde{p}(\overline{w}+) - \partial_{ww} \tilde{p}(\overline{w}-) \right) = & \left[ \frac{p''(\overline{w})}{\sigma_y \overline{w}} - \frac{\sigma_w(\overline{w})^2 \eta(\overline{w})}{\overline{w}^2} + \frac{\sigma_w(\overline{w}) \sigma_y}{\varphi^2 \eta(\overline{w})} \left( \frac{p(\overline{w})}{\eta(\overline{w})} - 1 \right) \right] \tilde{\varphi}(t) \\
+ & \left( \frac{\sigma_w(\overline{w})^2 (p'(\overline{w}) - 1)}{\varphi \eta(\overline{w})} - \frac{\sigma_w(\overline{w})^3 p''(\overline{w})}{\varphi^2 \eta(\overline{w})} \right) \tilde{p}
\end{split}
\quad (A.236)
\end{equation}

Now using the fact that $p'(\overline{w}) = p(\overline{w})/(\theta \overline{w}) - \sigma_y / \sigma_w(\overline{w})$, rewrite the coefficient on $\tilde{p}$:\begin{equation}
\frac{\sigma_w(\overline{w})^2 (p'(\overline{w}) - 1)}{\varphi \theta \eta(\overline{w}) \overline{w}} - \frac{\sigma_w(\overline{w})^3 p''(\overline{w})}{\theta w \sigma_y} = \frac{\sigma_w(\overline{w})^2}{\theta \overline{w} \varphi \eta(\overline{w})} \left( \frac{p(\overline{w})}{\overline{w}} - 1 \right) - \frac{\sigma_w(\overline{w}) \sigma_y}{\theta \overline{w} \varphi \eta(\overline{w})} - \frac{\sigma_w(\overline{w})^3 p''(\overline{w})}{\theta \overline{w} \sigma_y}
= \frac{\sigma_w(\overline{w})^2}{\theta \overline{w}} - \frac{\sigma_w(\overline{w}) \sigma_y}{\theta \overline{w} \varphi \eta(\overline{w})} - \frac{\sigma_w(\overline{w})^3 p''(\overline{w})}{\theta \overline{w} \sigma_y} \equiv - \frac{1}{\theta} C \quad (A.237)
\end{equation}

Rewriting the coefficient on $\tilde{\varphi}(t)$,\begin{equation}
\eta(\overline{w}) \left[ \frac{p''(\overline{w}) \sigma_w(\overline{w})^3}{\sigma_y \overline{w}} - \frac{\sigma_w(\overline{w})^2}{\overline{w}^2} + \frac{\sigma_w(\overline{w}) \sigma_y}{\varphi^2 \eta(\overline{w})} \left( \frac{p(\overline{w})}{\eta(\overline{w})} - 1 \right) \right] = \eta(\overline{w}) \left[ \frac{p''(\overline{w}) \sigma_w(\overline{w})^3}{\sigma_y \overline{w}} - \frac{\sigma_w(\overline{w})^2}{\overline{w}^2} + \frac{\sigma_w(\overline{w}) \sigma_y}{\varphi \eta(\overline{w})} \right] = \eta(\overline{w}) C \quad (A.238)
\end{equation}
Plugging this into the boundary condition equation (A.236),

\[
\frac{\sigma_w(w)^2}{2} (\partial_{ww}\tilde{p}(w^+)) - \partial_{ww}\tilde{p}(w^-) = \left( \eta(w)\widetilde{\varphi}(t) - \frac{\tilde{p}(w)}{\theta} \right) \left[ \frac{p''(w)\sigma_w(w)^3}{\sigma_y w} - \frac{\sigma_w(w)^2}{w^2} + \frac{\sigma_w(w)\sigma_y}{\varphi\eta(w)} \right] \quad (A.239)
\]

**Step 4: distribution.** Consider the KFE for \( g(w,t) \):

\[
\partial_t g(w,t) = -\partial_w(\mu_w(w,t)g(w,t)) + \frac{1}{2} \partial_{ww}(\sigma_w(w,t)^2 g(w,t)) \quad (A.240)
\]

Expanding,

\[
\partial_t \tilde{g} = -\partial_w(\mu_w(w)\tilde{g}) + \frac{1}{2} \partial_{ww}(\sigma_w(w)^2 \tilde{g}) - \partial_w(\tilde{\mu}_w(w)g(w)) + \partial_{ww}(\tilde{\sigma}_w\sigma_w(w)g(w)) \quad (A.241)
\]

Having computed \( \tilde{p} \), one can plug \( \tilde{\mu}_w \) and \( \tilde{\sigma}_w \). When the constraint is slack,

\[
\tilde{\sigma}_w = \frac{\sigma_w(w)^2}{\sigma_y} \partial_w\tilde{p} - \frac{\sigma_w(w)^2\eta(w)}{\sigma_y w} \tilde{\varphi}(t) \quad (A.242)
\]

\[
\tilde{\mu}_w = \frac{2\sigma_w(w)^3}{\sigma_y w} \partial_w\tilde{p} - \frac{2\sigma_w(w)^3\eta(w)}{\sigma_y w^2} \tilde{\varphi}(t) + w\tilde{r}(t) + \hat{\lambda}\tilde{n}(t) \quad (A.243)
\]

When it binds,

\[
\tilde{\sigma}_w = \frac{\sigma_w(w)^2}{\sigma_y} \partial_w\tilde{p} - \frac{\sigma_w(w)^2}{\theta w\sigma_y} \tilde{p} \quad (A.244)
\]

\[
\tilde{\mu}_w = \frac{2\sigma_w(w)^3}{\sigma_y\varphi\eta(w)} \left( \frac{p(w,t)}{\theta w} - 1 \right) \partial_w\tilde{p} - \frac{\sigma_w(w)^2}{\varphi^2\eta(w)} \left( \frac{p(w,t)}{\theta w} - 1 \right) \tilde{\varphi}(t) + w\tilde{r}(t) + \hat{\lambda}\tilde{n}(t) + \sigma_w(w)^2 \left[ 1 - \frac{2\sigma_w(w)}{\varphi\theta\eta(w)} \left( \frac{p(w,t)}{\theta w} - 1 \right) \right] \tilde{p} \quad (A.245)
\]

Aggregate regular country and intermediary wealth deviations are

\[
\tilde{w}(t) = \int \tilde{g}wdw \quad (A.246)
\]

\[
\tilde{n}(t) = -\frac{\rho}{\tilde{p}}\tilde{w}(t) \quad (A.247)
\]

The US tree price satisfies

\[
\hat{p}(t)q = n(t) + w(t) - \int p(w,t)g(w,t)dt \quad (A.248)
\]
Expanding,

\[ \tilde{pq} = \tilde{n}(t) \left( 1 - \frac{\rho}{\tilde{\rho}} \right) - \int \tilde{p}g(w)dw - \int \tilde{q}p(w)dw \]  

(A.249)

The deviations in the interest rate and the global factor satisfy

\[ \tilde{r}(t) = \frac{\partial \tilde{p}}{\tilde{p}} - \frac{r\tilde{p}}{\tilde{p}} \]  

(A.250)

\[ \tilde{\varphi}(t) = \gamma \tilde{n}(t) + n\tilde{\gamma}(t) \]  

(A.251)

These close the linearized model.

**Step 5: numerical procedure.** The discrete approximation of the PDE for \( \tilde{p} \) can be written as

\[
\left( A_p - \frac{1}{dt} \right) p(t) = J_{rhs,r} r(t) + J_{rhs,n} n(t) + J_{rhs,\varphi} \varphi(t) - \frac{1}{dt} p(t+1)
\]  

(A.252)

Denoting \( M_1 = (A_p - 1/dt)^{-1}, M_2 = 1/dt, \) and \( M_3 = -M_1M_2, \)

\[
p(t) = M_1J_{rhs,r} r(t) + M_1J_{rhs,n} n(t) + M_1J_{rhs,\varphi} \varphi(t) + M_3 p(t+1)
\]  

\[
= \sum_{s=0}^{T-t} (M_3)^s M_1 J_{rhs,r} r(t+s) + \sum_{s=0}^{T-t} (M_3)^s M_1 J_{rhs,n} n(t+s) + \sum_{s=0}^{T-t} (M_3)^s M_1 J_{rhs,\varphi} \varphi(t+s)
\]  

\[
= \sum_{s=0}^{T-t} j_{p,r}(s) r(t+s) + \sum_{s=0}^{T-t} j_{p,n}(s) n(t+s) + \sum_{s=0}^{T-t} j_{p,\varphi}(s) \varphi(t+s)
\]  

(A.253)

Here \( M_1, M_2, \) and \( M_3 \) have to be corrected to incorporate the boundary condition at \( \bar{w}. \)

The discrete approximation of the KFE for \( \tilde{g} \) is

\[
\left( A_g + \frac{1}{dt} \right) g(t+1) = -A_1 \mu_w(t) + A_2 \sigma_w(t) + \frac{1}{dt} g(t)
\]  

(A.254)

Here the matrix \( A_1 \) discretizes the operator \( \partial_w \cdot g(w) \cdot \), and \( A_2 \) discretizes \( \partial_{ww} \cdot \sigma_w(w) \cdot g(w) \cdot \).

Denoting \( M_4 = (A_g + 1/dt)^{-1}, M_5 = -M_4A_1, M_6 = M_4A_2, \) and \( M_g = M_4M_2, \)

\[
g(t+1) = M_5 \mu_w(t) + M_6 \sigma_w(t) + M_g g(t)
\]  

\[
= \sum_{s=0}^{t-1} (M_g)^s M_5 \mu_w(t-s) + \sum_{s=0}^{t-1} (M_g)^s M_6 \sigma_w(t-s) + (M_g)^{t-1} g(0)
\]  

\[
= \sum_{s=0}^{t-1} j_{g,\mu}(s) \mu_w(t-s) + \sum_{s=0}^{t-1} j_{g,\sigma}(s) \sigma_w(t-s) + (M_g)^{t-1} g(0)
\]  

(A.255)
The drift deviations can be written as

\[
\mu_w(t) = J_{\mu,p} p(t) + J_{\mu,r}^\text{direct} r(t) + J_{\mu,n}^\text{direct} n(t) + J_{\mu,\varphi}^\text{direct} \varphi(t) = \left( \sum_{s=0}^{T-t} J_{p,r}(s) + J_{\mu,r}^\text{direct} \delta_{s,0} \right) r(t + s) \\
+ \left( \sum_{s=0}^{T-t} J_{p,n}(s) + J_{\mu,n}^\text{direct} \delta_{s,0} \right) n(t + s) + \left( \sum_{s=0}^{T-t} J_{p,\varphi}(s) + J_{\mu,\varphi}^\text{direct} \delta_{s,0} \right) \varphi(t + s) \\
= \sum_{s=0}^{T-t} J_{\mu,r}(s) r(t + s) + \sum_{s=0}^{T-t} J_{\mu,n}(s) n(t + s) + \sum_{s=0}^{T-t} J_{\mu,\varphi}(s) \varphi(t + s) \quad \text{(A.256)}
\]

The volatility deviations are

\[
\sigma_w(t) = J_{\sigma,p} p(t) + J_{\sigma,r}^\text{direct} r(t) + J_{\sigma,n}^\text{direct} n(t) + J_{\sigma,\varphi}^\text{direct} \varphi(t) = \left( \sum_{s=0}^{T-t} J_{p,r}(s) + J_{\sigma,r}^\text{direct} \delta_{s,0} \right) r(t + s) \\
+ \left( \sum_{s=0}^{T-t} J_{p,n}(s) + J_{\sigma,n}^\text{direct} \delta_{s,0} \right) n(t + s) + \left( \sum_{s=0}^{T-t} J_{p,\varphi}(s) + J_{\sigma,\varphi}^\text{direct} \delta_{s,0} \right) \varphi(t + s) \\
= \sum_{s=0}^{T-t} J_{\sigma,r}(s) r(t + s) + \sum_{s=0}^{T-t} J_{\sigma,n}(s) n(t + s) + \sum_{s=0}^{T-t} J_{\sigma,\varphi}(s) \varphi(t + s) \quad \text{(A.257)}
\]

Plugging,

\[
g(t + 1) = \sum_{s=0}^{T-t} J_{g,\mu}(s) \sum_{u=0}^{T-t+s} J_{\mu,r}(u) r(t - s + u) + \sum_{s=0}^{T-t} J_{g,\mu}(s) \sum_{u=0}^{T-t+s} J_{\mu,n}(u) n(t - s + u) \\
+ \sum_{s=0}^{T-t} J_{g,\mu}(s) \sum_{u=0}^{T-t+s} J_{\mu,\varphi}(u) \varphi(t - s + u) + \sum_{s=0}^{T-t} J_{g,\sigma}(s) \sum_{u=0}^{T-t+s} J_{\sigma,r}(u) r(t - s + u) \\
+ \sum_{s=0}^{T-t} J_{g,\sigma}(s) \sum_{u=0}^{T-t+s} J_{\sigma,n}(u) n(t - s + u) + \sum_{s=0}^{T-t} J_{g,\sigma}(s) \sum_{u=0}^{T-t+s} J_{\sigma,\varphi}(u) \varphi(t - s + u) \\
+ (M_g)^{t-1} g(0) \quad \text{(A.258)}
\]

Changing the order of summation,

\[
g(t + 1) = \sum_{u=0}^{T-t} J_{g,\mu}(u) J_{\mu,r}(u + s - t) r(s) + \sum_{u=0}^{T-t} J_{g,\mu}(u) J_{\mu,n}(u + s - t) n(s) \\
+ \sum_{u=0}^{T-t} J_{g,\mu}(u) J_{\mu,\varphi}(u + s - t) \varphi(s) + \sum_{u=0}^{T-t} J_{g,\sigma}(u) J_{\sigma,r}(u + s - t) r(s) \\
+ \sum_{u=0}^{T-t} J_{g,\sigma}(u) J_{\sigma,n}(u + s - t) n(s) + \sum_{u=0}^{T-t} J_{g,\sigma}(u) J_{\sigma,\varphi}(u + s - t) \varphi(s) + (M_g)^{t-1} g(0) \quad \text{(A.259)}
\]
Initial revaluation \( g(0) \) comes from the jump in prices: \( g(0) = A^{\text{reval}} p(0) \), so \( g(t + 1) \) is

\[
g(t + 1) = \sum_{s=1}^{T} J_{g,\mu,r}^{\text{accum}}(t, s) r(s) + \sum_{s=1}^{T} J_{g,\mu,n}^{\text{accum}}(t, s) n(s) + \sum_{s=1}^{T} J_{g,\mu,\varphi}^{\text{accum}}(t, s) \varphi(s) \\
+ \sum_{s=1}^{T} J_{g,\sigma,r}^{\text{accum}}(t, s) r(s) + \sum_{s=1}^{T} J_{g,\sigma,n}^{\text{accum}}(t, s) n(s) + \sum_{s=1}^{T} J_{g,\sigma,\varphi}^{\text{accum}}(t, s) \varphi(s) \\
+ \sum_{s=1}^{T} J_{g,r}^{\text{reval}}(t, s) r(s) + \sum_{s=1}^{T} J_{g,n}^{\text{reval}}(t, s) n(s) + \sum_{s=1}^{T} J_{g,\varphi}^{\text{reval}}(t, s) \varphi(s) \tag{A.260}
\]

Here the accumulation Jacobians are

\[
J_{g,\mu,r}^{\text{accum}}(t, s) = \sum_{u=0}^{t-1} J_{g,\mu}(u) J_{\mu,r}(u + s - t) = J_{g,\mu,r}^{\text{accum}}(t + 1, s + 1) - J_{g,\mu}(t) J_{\mu,r}(s) \tag{A.261}
\]

\[
J_{g,\mu,n}^{\text{accum}}(t, s) = \sum_{u=0}^{t-1} J_{g,\mu}(u) J_{\mu,n}(u + s - t) = J_{g,\mu,n}^{\text{accum}}(t + 1, s + 1) - J_{g,\mu}(t) J_{\mu,n}(s) \tag{A.262}
\]

\[
J_{g,\mu,\varphi}^{\text{accum}}(t, s) = \sum_{u=0}^{t-1} J_{g,\mu}(u) J_{\mu,\varphi}(u + s - t) = J_{g,\mu,\varphi}^{\text{accum}}(t + 1, s + 1) - J_{g,\mu}(t) J_{\mu,\varphi}(s) \tag{A.263}
\]

\[
J_{g,\sigma,r}^{\text{accum}}(t, s) = \sum_{u=0}^{t-1} J_{g,\sigma}(u) J_{\sigma,r}(u + s - t) = J_{g,\sigma,r}^{\text{accum}}(t + 1, s + 1) - J_{g,\sigma}(t) J_{\sigma,r}(s) \tag{A.264}
\]

\[
J_{g,\sigma,n}^{\text{accum}}(t, s) = \sum_{u=0}^{t-1} J_{g,\sigma}(u) J_{\sigma,n}(u + s - t) = J_{g,\sigma,n}^{\text{accum}}(t + 1, s + 1) - J_{g,\sigma}(t) J_{\sigma,n}(s) \tag{A.265}
\]

\[
J_{g,\sigma,\varphi}^{\text{accum}}(t, s) = \sum_{u=0}^{t-1} J_{g,\sigma}(u) J_{\sigma,\varphi}(u + s - t) = J_{g,\sigma,\varphi}^{\text{accum}}(t + 1, s + 1) - J_{g,\sigma}(t) J_{\sigma,\varphi}(s) \tag{A.266}
\]

The revaluation Jacobians are

\[
J_{g,r}^{\text{reval}}(t, s) = (M_g)^{t-1} A^\text{reval} J_{p,r}(s) \tag{A.267}
\]

\[
J_{g,n}^{\text{reval}}(t, s) = (M_g)^{t-1} A^\text{reval} J_{p,n}(s) \tag{A.268}
\]

\[
J_{g,\varphi}^{\text{reval}}(t, s) = (M_g)^{t-1} A^\text{reval} J_{p,\varphi}(s) \tag{A.269}
\]

The accumulation Jacobians can be computed recursively. This recursive procedure is the analog of the fake-news algorithm. The initial conditions are \( J_{g,\mu,r}^{\text{accum}}(t, 1) = J_{g,\mu}(t - 1) J_{\mu,r}(0) \) and \( J_{g,\mu,r}^{\text{accum}}(1, s) = J_{g,\mu}(0) J_{\mu,r}(s - 1) \) for \( r \) and analogously for \( n \) and \( \varphi \). The initial conditions for \( \sigma \) parts of the Jacobian are identical.

With these Jacobians at hand, it is possible to compute the Jacobian of any moment of the
distribution and any function of $w$. Specifically, aggregate wealth of the regular countries is

$$w(t) = \sum_{s=1}^{T} W' J^\text{total}_{g,r}(s, t) \mathbf{r}(s) + \sum_{s=1}^{T} W' J^\text{total}_{g,n}(s, t) \mathbf{n}(s) + \sum_{s=1}^{T} W' J^\text{total}_{g,\varphi}(s, t) \varphi(s)$$  \hspace{1cm} (A.270)

The deviation of the US tree price is

$$\hat{p}(t) = w(t) \frac{1}{q} \left(1 - \frac{\hat{\rho}}{\rho}\right) - \frac{1}{q} P' g(t) - \frac{1}{q} G' p(t)$$

$$= \frac{1}{q} \sum_{s=1}^{T} \left[ \left(1 - \frac{\hat{\rho}}{\rho}\right) W' - P' \right] J^\text{total}_{g,r}(s, t) - G' J_{p,r}(s - t) \right] \mathbf{r}(s)$$

$$+ \frac{1}{q} \sum_{s=1}^{T} \left[ \left(1 - \frac{\hat{\rho}}{\rho}\right) W' - P' \right] J^\text{total}_{g,n}(s, t) - G' J_{p,n}(s - t) \right] \mathbf{n}(s)$$

$$+ \frac{1}{q} \sum_{s=1}^{T} \left[ \left(1 - \frac{\hat{\rho}}{\rho}\right) W' - P' \right] J^\text{total}_{g,\varphi}(s, t) - G' J_{p,\varphi}(s - t) \right] \varphi(s)$$  \hspace{1cm} (A.271)

Here $G$ is the vectorized steady-state density, $P$ is the vectorized steady-state price, and $W$ is the wealth grid. The convention is that $J_{p,r}(t - s) = 0$ whenever $s > t$, and the same for $n$ and $\varphi$.

**Shocks to output.** All equations are very similar when there are shocks to output $\tilde{\nu}(t)$ and $\tilde{\hat{\nu}}(t)$ instead of risk-taking capacity $\tilde{\gamma}(t)$. Indeed, $\tilde{\gamma}(t)$ only appears explicitly at the very end in $\tilde{\varphi}(t) = \gamma \tilde{n}(t) + n \gamma(t)$. In case of output shocks, deviations $\tilde{\varphi}(t)$ and $\tilde{n}(t)$ still enter all equations separately but the relationship is simpler, $\tilde{\varphi}(t) = \gamma \tilde{n}(t)$.

One substantial difference is that $\tilde{\nu}(t)$ directly enters the Kolmogorov backward equation for risky asset prices, while $\tilde{\hat{\nu}}(t)$ enters the pricing equation for the safe asset. It is straightforward to add these deviations to all equations.
